STERNUM PUNCTURE

I. THE FINDINGS IN NORMAL INDIANS

By L. EVERARD NAPIER, M.R.C.P. (Lond.)

Professor of Tropical Medicine

and

P. C. SEN GUPTA, M.B. (Cal.)

Clinical Assistant

Calcutta School of Tropical Medicine

BONE puncture as an aid to accurate diagnosis of blood diseases and to the study of their aetiology has only come into general use during the last few years; the main reason for this was that the methods hitherto used for obtaining material from the bones were comparatively difficult, and usually painful unless an anæsthetic was used. The obvious advantages to be gained by studying the marrow during life led workers to turn their attention again to the subject of bone puncture and Young and Osgood (1935) devised a method of sternum puncture through the sterno-manubrial junction. The senior writer attempted to follow their technique, first practising on the cadaver, but found it difficult, and, with the non-rigid needle at his disposal, dangerous, as on one occasion—fortunately in the cadaver—the needle was deflected by the bone and pierced the mediastinum. However, whilst in London during the summer vacation of 1936 he was shown a simple method of sternum puncture by Professor Wits. Professor Wits used a special needle of a pattern which, we understand, was first introduced in Egypt. We found that with this needle sternum puncture presented no difficulties or risks, and caused no more pain than most patients expect to suffer during their treatment in hospital. We have therefore adopted this procedure as a routine in the investigation of anemia and certain other diseases.

At this time the only available standards for sternum puncture in normal persons were those of Young and Osgood (*loc. cit.*), and of a few other workers quoted by them; some notes on normal findings in sternum puncture were received from Dr. C. R. Das Gupta who had made them from a clinical lecture given by Professor Wits.

It appeared to us that the first desiderata for a study of the cytology of bone marrow were a fixed nomenclature for the cells we encountered and a normal standard for comparison. Therefore in order to get a clear idea in our own minds regarding the identity of the various types of cell encountered, we had a number of coloured drawings made of each type, and we attempted to describe each as accurately as possible and to define the differentiating points. In the past we have found that European and American standards do not always coincide with

Indian standards; we therefore thought it essential to carry out sternum-puncture counts in a certain number of normal individuals. Sternum puncture is not entirely painless and volunteers ready to subject themselves to the operation were not easily found. We obtained 10 such volunteers and, though the number is small, until we add to it, as we propose to do whenever opportunity arises, we were compelled to use the findings in these 10 cases as a basis for the calculation of a provisional standard.

In this report we shall confine ourselves to these observations made on normal individuals. In the plate we are publishing with this paper there are only one or two samples of each type of cell, stained by one method, but with subsequent papers we hope to include other plates in which we shall give further examples of normal cells, stained by other methods, as well as other cells not usually encountered in the bone marrow of the normal individual.

Technique of sternum puncture

Equipment.—The sternum puncture needle, 5 c.cm. and 2 c.cm. Record syringes, 2 per cent solution of novocaine, absolute alcohol, tincture of iodine, collodion and cotton-wool. The needle and the syringes are sterilized either by boiling or in an autoclave.

The sternum puncture needle

The needle used for sternum puncture is shown below (figure 1). It is made of rustless steel and the bore is about the same as that of a lumbar puncture needle. The guard C on the needle can be moved so as to adjust the depth of the puncture. Usually the guard has to be fixed at a distance of one quarter to half an inch from the tip, in order that the marrow may be reached. This distance will vary with the thickness of the skin and subcutaneous tissue of the thoracic wall, and it may be found advisable to readjust the guard after the needle has reached the periosteum, before it is pushed through the outer plate into the marrow cavity. The stylet A is kept in while the puncture is being made and is withdrawn after the cavity is reached.

Procedure

The skin over the sternum is cleaned thoroughly with alcohol. The best site for the puncture is just to one side of the middle line at the level of the third intercostal space. This area is first anæsthetized by infiltration with a two per cent solution of novocaine.

Some solution is first injected into the skin with a fine needle attached to a 2-c.cm. syringe, then the needle is pushed down to the periosteum and the rest of the solution injected. About 1 c.cm. is usually sufficient. After an interval of five minutes or so the actual puncture is made.

The needle is held with the knob of the stylet in the palm of the hand and the needle itself

between the thumb and index finger, the latter on the guard C of the needle. Pressure is applied and the skin and subcutaneous tissues are pierced; a rotary movement will then facilitate puncture of the outer plate of the sternum. As the external plate of the sternum is pierced and the marrow cavity is entered, there is a sensation of loss of resistance, just as is felt on entering the spinal canal during lumbar puncture. The stylet is now taken out, the 5-cm. Record syringe is attached to the end of the needle, and the marrow blood is aspirated. When the fluid is aspirated the patient feels a dragging pain which is

Fig. 1.—Needle B with stylet A removed: movable guard C (actual size).

a guide as to whether the needle is in the marrow cavity or not. As near as possible to 2 c.cm. of marrow (sinusoidal) blood is removed and the syringe and the sternum puncture needle are withdrawn; the puncture over the skin is sealed with collodion. The syringe is inverted several times so as to mix the contents thoroughly and then small drops are placed on clean slides and smears are made. The rest of the fluid is put into an oxalate tube*.

* Potassium oxalate is used to prevent coagulation. For 2 c.cm. of blood 4 milligrammes of potassium oxalate are used. A small measured volume of solution containing this amount of oxalate is put into the tube which is then dried in a hot-air sterilizer.

Tables I and IA giving a summary of the hæmatological findings in the sinusoidal blood from the sternum of 10 normal male Indians

TABLE I

	Range	Mean	Standard deviation
Hæmoglobin in grammes per 100 c.c.	12.1 to 14.85	13.43	± 0.93
Red cells per c.mm. in millions	4.40 to 5.45	4.99	± 0.40
Reticulocytes—percentage of red cells	0.3 to 1.6	0.75	± 0.39
Total nucleated cells per c.mm.	32,500 to 116,000	53,500	± 26,500
Nucleated red cells—number per c.mm.	6,987 to 27,260	13,824	± 6,420
Nucleated red cells—percentage of total nucleated cells	20 to 31.5	25.75	± 4.07
Leucocytes—percentage of total nucleated cells	68.5 to 80.0	74.25	± 4.07
Granulocytes—percentage of total nucleated cells	56.5 to 70.8	64.40	± 5.10
Non-granular leucocytes—percentage of total leucocytes	7.0 to 14.0	9.82	± 2.43
Leucocyte/erythroblast ratio	2.17 to 4.00	2.97	± 0.67

Not more than 2 c.cm. of blood is aspirated, because, if more is drawn, there is a probability of causing negative pressure in the marrow cavity, of drawing in blood from the vessels in the locality and of diluting the sinusoidal blood; it is probably impossible to prevent this occurring entirely, therefore a constant amount of blood is drawn to obviate gross differences in the degree of dilution in the samples taken from different persons. The syringe is inverted several times in order that the contents may be mixed thoroughly. This is necessary because the fluid that comes out in the beginning is probably not the same as regards cellular content as the fluid that comes out towards the end of the aspiration.

Examination of material

The oxalated specimen was examined for:—
 hæmoglobin content;
 red cell enumeration;
 reticulocyte percentage; and
 nucleated cell enumeration.

The slides were stained by Leishman's stain and the proportions of the different nucleated cell elements were accurately estimated. (Other staining methods have also been used, but in this paper only Leishman-stained specimens are depicted and described.)

The criteria on which we identified the different cells are given below. The findings in the 10 'normal' male Indians are summarized in tables I and IA.

Description of individual cells

Megaloblast.—The earliest cell in the erythrocyte series.

Size—mean diameter— 16μ to 21μ (mean of 25 cells = $18.1 \pm 1.64\mu$).

(1) The cytoplasm is deeply basophilic (greyish-blue colour).

(2) The nucleus is large, round or oval, occupies most of the cell, and is usually somewhat eccentrically placed. The chromatin network is fine and delicate and a fine granular effect is produced; nucleoli may sometimes be seen.

Erythroblast

Size—mean diameter— 12μ to 18μ (mean of 25 cells = $14.38 \pm 1.67\mu$), that is, slightly smaller

TABLE IA

						PERCENTUM OF NUCLEATED CELLS	
						Range	Mean
Nucleated red cells.	Megaloblasts	0 to 1.5	0.7
	Erythroblasts	0.4 to 10.0	3.4
	Normoblasts	16.0 to 25.5	21.6
	Myeloblasts	0.4 to 1.5	1.2
	Premyelocytes	0 to 1.5	0.7
	Myelocytes—						
	Neutrophil	1 to 9.5	4.4
	Eosinophil	0.4 to 2.0	1.3
	Basophil	None observed	

PLATE I: AN EXPLANATION

In the representation of colour each artist will render his own interpretation which will differ, however slightly, from that of other artists.

In the making of a coloured plate of blood cells there are three separate artists concerned, the one who makes the original painting, the lithographer, and the printer.

Thus, each deviation from the original is liable not only to perpetuation but to a threefold exaggeration and it is almost impossible to ensure that the final result is an exact representation of the original.

In this case, the work has been done excellently and the plate is a better representation of the actual cells, as seen in the microscope, than are the plates in many textbooks and atlases of hæmatology: nevertheless, we think that the following comments may assist our readers:—

The cytoplasm in the premyelocyte (B2) is too pink; there should be more blue in it; and one nucleolus in the nucleus is a little too prominent.

In the first large mononuclear cell (C) the reddish-purple dots in the cytoplasm are far too large and prominent. In the second cell these are depicted more correctly.

The cytoplasm in the plasma cell (E) is too grey.

The cytoplasm in the megakaryocyte is too pink; there should be more light blue in this.

Size—mean diameter— 5.5μ to 13.5μ (mean of 25 cells = 9.48μ).

(1) The cytoplasm contains hæmoglobin; the colour varies from a light grey to the light dull red of the normal red cell.

(2) The nucleus may be similar to that of the erythroblast, only smaller and more darkly stained, or in older normoblasts it is very dense, stains quite black like an ink drop, and appears to stand out from the cytoplasm; this form varies in size from a full-sized nucleus occupying about half the cell down to a small round dot. It may take either a clover-leaf or a rosette form just before it is extruded. It is usually eccentrically placed.

Myeloblast

The stem cell of the myeloid series of leucocytes.

Size—mean diameter— 14.5μ to 19.5μ (mean of 25 cells = $16.58 \pm 1.26\mu$).

Nucleoli may or may not be present.

DESCRIPTION OF PLATE I

- A. *Red cell series.*
1. Megaloblasts.
 2. Erythroblasts.
 3. Young normoblasts.
 4. More mature normoblasts, with pyknotic nucleus and hæmoglobinized cytoplasm.
- B. *Myeloid series.*
1. Myeloblast.
 2. Premyelocyte.
 3. Neutrophil myelocytes.
 4. Eosinophil myelocytes.
 5. Basophil myelocyte.
 6. Granulocyte, neutrophil, young form.
 7. " " band forms.
 8. " " segmented forms.
 9. " eosinophil.
 10. " basophil.
- C. Large mononuclears.
- D. Lymphocytes.
1. Large.
 2. Small.
- E. Plasma cell.
- F. Megakaryocyte.

TABLE IA

					PERCENTUM OF NUCLEATED CELLS	
					Range	Mean
Nucleated red cells.	Megaloblasts	0 to 1.5	0.7
	Erythroblasts	0.4 to 10.0	3.4
	Normoblasts	16.0 to 25.5	21.6
Granular leucocytes.	Myeloblasts	0.4 to 1.5	1.2
	Premyelocytes	0 to 1.5	0.7
	Myelocytes—					
	Neutrophil	1 to 9.5	4.4
	Eosinophil	0.4 to 2.0	1.3
	Basophil	None observed	
	Mature granulocytes—					
	Young forms	6.4 to 15	9.7
	Band forms	14.0 to 38.5	25.3
	Segmented neutrophil	6.5 to 25.6	16.8
	Eosinophil	0 to 7.6	4.7
	Basophil	0 to 1	0.2
	Ratio: immature/mature	0.066 to 0.235	0.138
Non-granular leucocytes.	Lymphocytes	3 to 12	6.25
	Large mononuclears	1.2 to 7	3.0
	Plasma cells	0 to 1.6	0.6

than the megaloblast. Often seen in pairs connected by a small strand or filament of cytoplasm.

(1) The cytoplasm is deeply basophilic, usually rather a brighter blue than that of the megaloblast.

(2) The nucleus occupies a slightly greater proportion of the cell, but as the whole cell is smaller, it is usually slightly smaller than that of the megaloblast; also the chromatin is much denser and coarser and gives a mottled effect, or there may be a cartwheel-like arrangement of the chromatin.

Normoblast

Size—mean diameter— 5.5μ to 13.5μ (mean of 25 cells = 9.48μ).

(1) The cytoplasm contains haemoglobin; the colour varies from a light grey to the light dull red of the normal red cell.

(2) The nucleus may be similar to that of the erythroblast, only smaller and more darkly stained, or in older normoblasts it is very dense, stains quite black like an ink drop, and appears to stand out from the cytoplasm; this form varies in size from a full-sized nucleus occupying about half the cell down to a small round dot. It may take either a clover-leaf or a rosette form just before it is extruded. It is usually eccentrically placed.

Myeloblast

The stem cell of the myeloid series of leucocytes.

Size—mean diameter— 14.5μ to 19.5μ (mean of 25 cells = $16.58 \pm 1.26\mu$).

(1) The cytoplasm is pale blue, without any granules.

(2) The nucleus is more-or-less rounded and very finely meshed. It stains a faint purple colour and does not become denser at the edges (i.e., there is no nuclear membrane). There are usually 3 or 4 nucleoli.

Premyelocyte

Size—almost the same as that of the myeloblast. Mean diameter 14.5μ to 20μ (mean of 25 cells = $16.9 \pm 1.55\mu$).

The cytoplasm and the nucleus are very similar to those of the myeloblast, but the former contains fine reddish-blue granules. Nucleoli may or may not be present.

DESCRIPTION OF PLATE I

A. Red cell series.

1. Megaloblasts.
2. Erythroblasts.
3. Young normoblasts.
4. More mature normoblasts, with pyknotic nucleus and haemoglobinized cytoplasm.

B. Myeloid series.

1. Myeloblast.
2. Premyelocyte.
3. Neutrophil myelocytes.
4. Eosinophil myelocytes.
5. Basophil myelocyte.
6. Granulocyte, neutrophil, young form.
7. " " band forms.
8. " " segmented forms.
9. " eosinophil.
10. " basophil.

C. Large mononuclears.

D. Lymphocytes.

1. Large.
2. Small.

E. Plasma cell.

F. Megakaryocyte,

Myelocyte

Size—mean diameter— 14.5μ to 19μ (mean of 25 cells = $16.72 \pm 0.93\mu$).

(1) The cytoplasm is a pale greyish-blue and contains the characteristic granules, which are either neutrophilic, eosinophilic, or basophilic. According to the staining character of the granules these are called neutrophilic, eosinophilic, or basophilic myelocytes and they give rise to the neutrophil, eosinophil, or basophil polymorphonuclear leucocytes (granulocytes) found normally in the blood.

(2) The nucleus is oval or rounded, slightly coarser than those of its genetic predecessors, and purple staining.

band, which may be folded and take various shapes, e.g., L-, C-, S-, or Z-shaped, or may be coiled. There is no division of nucleus at this stage.

	Range	Sizes Mean of 25 cells and standard deviation
Young	12μ to 19.5μ	15.18 ± 2.12
Band	11.5μ to 17μ	13.32 ± 1.33
Segmented	11.5μ to 14.5μ	13.18 ± 0.83
Eosinophil	12μ to 17.5μ	14.78 ± 1.55
Basophil	10μ to 14.5μ	$12.04^* \pm 1.26$

* Mean of 13 cells only.

Large mononuclear leucocyte

Size—mean diameter— 13μ to 21μ (mean of 25 cells = $16.78 \pm 1.98\mu$).

Fig. 2.—Needle in position after the marrow cavity has been penetrated.

Granulocytes

The mature myeloid leucocyte.

These are divided into three classes, neutrophils, eosinophils, and basophils, according to the staining properties of the granules contained in the cytoplasm. In the neutrophils the cytoplasm is oxyphilic and contains fine granules. In the eosinophils and basophils the granules are coarse. The nucleus of the fully-mature cell is divided into two or more segments (*segmented forms*). Between the precursor cell (the myelocyte) and the fully-mature segmented forms, there are intermediate forms, the *young* and the *band forms*. The *young granulocyte* has a nucleus which is kidney-shaped or slightly indented on one side. In the *band form* of granulocytes, the nucleus is like a ribbon or

(1) The cytoplasm stains a pale dull blue and shows very fine reddish-blue granules. It may contain vacuoles.

(2) The nucleus is reniform, horse-shoe-shaped, or even convoluted in the mature cells, and in the younger cells it is oval or even rounded. It is eccentrically placed and stains a pale violet colour. It shows a characteristic strand arrangement of chromatin, and, where the strands of chromatin cross, the staining appears darker.

Lymphocytes

Size—mean diameter—

large lymphocyte— 12μ to 15μ .

small lymphocyte— 7μ to 12μ (mean of 25 cells = $10.6 \pm 1.28\mu$.)

(1) The cytoplasm is clear sky-blue and in the small (mature) lymphocyte it is like a thin rim round the nucleus. In the larger forms it is more plentiful and may occasionally contain a few fine reddish-blue granules.

(2) The nucleus stains deeply and is usually composed of heavy masses of chromatin, particularly towards the periphery, whilst between these masses may be seen paler-staining areas. The nucleus occupies most of the cell, leaving a comparatively narrow band of cytoplasm.

This cell is distinguished from the large mononuclear by the clear blue cytoplasm, without, or with few, fine granules and by the darker staining of the nucleus.

a large lobulated deeply-stained nucleus without nucleoli.

Discussion

The material which is obtained by this procedure is neither peripheral blood (obviously) nor bone marrow, but is blood from both the patent and the closed sinusoidal spaces in the haemopoietic tissue of the bone marrow, in which are mixed a few cells detached from the walls of these sinuses by the intruding needle, or by the act of aspiration. The extent to which the detached tissue cells are added to the sinusoidal blood probably varies with each puncture and constitutes the weakness of the procedure from the point of view of obtaining a true and unvarying picture of bone marrow

Fig. 3.—The stylet has been removed and sinusoidal blood is being drawn into a Record syringe.

Plasma cell

Size—mean diameter— 14μ to 18μ (mean diameter of 25 cells = $15.5 \pm 1.14\mu$).

The cell is usually oval.

(1) The cytoplasm is very plentiful, a dull rather dark blue, occasionally with reddish-blue granules.

(2) the nucleus is dark staining, usually with a distinct cart-wheel pattern, eccentric, with a diameter less than half that of the whole cell.

Megakaryocyte

Size—a huge cell, 32μ to 53μ , mean 45μ . Very amoeboid with irregular-shaped cytoplasm which takes the stain badly becoming a washed-out pink colour with fine granules, giving it a frosted-glass effect, around the nucleus, but often with the peripheral portion of the cytoplasm clear, and its edge ill-defined: it has

haemopoietic activity. However, the extreme variations in a single subject that have been reported by some workers, and the differences in the normals given by different workers can probably to some extent be accounted for by variations or defects in the technique employed, e.g., by the failure to remove a small and constant amount of blood, by failure to mix the blood before making smears, or by making counts from one part of the blood film only.

Zanaty (1937) has pointed out that wide variations may exist in the total nucleated-cell counts and that little idea can be obtained from these counts of the activity of the bone marrow: this is probably true. Our normal series was a very small one and possibly for that reason we did not get the extreme figures that he quotes, but from our experience of sternum puncture in diseased conditions we believe that the correlation between haemopoietic activity and the total

nucleated-cell count is more complete than this writer suggests.

The hæmoglobin was fairly constant, between 1 gramme and 1.5 gramme less than that of the venous blood in the same individual; similarly the red cell count in the sinusoidal blood was about half a million less than in the venous.

The reticulocyte percentage was a matter of surprise to us; it was in every instance within the normal range of that in the peripheral blood and the mean of the whole series was only a small fraction above the peripheral-blood mean. This is, however, the same order of finding as that of other workers, with the exception of Young and Osgood (*loc. cit.*) who give a higher range (see table II).

been confirmed by many other workers in India and in Europe.

Megakaryocytes did not appear in our counts though we have seen them in the sinusoidal blood of apparently normal individuals. Nor in this series did we identify any cells as monoblasts or lymphoblasts. We did not include in our counts cell fragments or 'disintegrating cells'; we identified to our own satisfaction practically all the nucleated cells that we saw, and we do not believe that more than a fraction of a per cent of 'disintegrating cells' or fragmented nuclei that we omitted to identify will have been included in our total nucleated-cell counts.

Our immature/mature myeloid cell ratio was apparently about the same as that of Young

Myeloid—							
Erythroblast ratio	7.7 : 1 to 4.17 : 1	4.86 : 1	5.83 : 1 to 5.39 : 1	8.29 : 1 to 2.00 : 1	..	2.97 : 1	..

* This table is composed from the tables given by Young and Osgood (1935), and by Zanaty (1937). Some rearrangement, to correlate the two tables and to bring them into line with our own nomenclature, has had to be made. The figures have not been checked from the original publications.

Our myeloid/erythroblast ratio is however lower than that of any other workers, though all our findings were within the range given by Young and Osgood.

The megaloblast is a continual subject of controversy and many writers claim that it is not found in the normal bone marrow: we can only say that in most of our 'normal' smears, we found cells that were indistinguishable from the megaloblasts with which we are quite familiar in sinusoidal-blood smears from cases of anæmia and whose identity as megaloblasts has

and Osgood, but was lower than that of other observers.

Summary

The technique of sternum puncture is described.

The various cells found in the normal sinusoidal blood of Indians are described and depicted in a coloured plate.

Tables showing the range and mean number of each different type of cell in the normal

(Continued at foot of opposite page)

ADULT FILARIAL WORM OF UNKNOWN SPECIES REMOVED FROM THE SKIN OF A HUMAN SUBJECT

By H. R. RISHWORTH, F.M.C.S.

District Medical Officer, G. I. P. Ry.

Late Honorary Surgeon, St. George's Hospital, Bombay

ADULT filarial worms have occasionally been recorded from the human eye in India, but the removal of a living and intact specimen from the subcutaneous tissue of a living subject has so far not been recorded in this country. A remarkable feature of the case here noted is the removal of specimens both from the eye and the skin of the same patient. The skin specimen is in a good state of preservation and from its morphology would appear to belong to a new species.

Sunder Rao (1933) records and illustrates two worms under the left conjunctiva of a Jewess who had suffered from elephantiasis for four years. An attempt to obtain the worms for examination failed, one disappearing into the tissues during section and the other being lost in the process of extraction in some unaccountable manner. Several members of the patient's family were infected with *Wuchereria bancrofti* and the presumption is that these worms were adult *W. bancrofti*.

Charles (1920) reported the removal of a living adult filaria from the eye of an adult male, the specimen being later identified by Sewell as *Filaria conjunctiva* Addario, 1885.

Das Gupta (1921) reported the removal at Ramporehaut of two live worms from a cyst in the outer canthus of a Mohammedan. These worms have not been identified.

Wright, Seetharama Iyer and Pandit (1935) described an adult male filaria from the anterior chamber of the eye of a man in Madras.

Loa loa occurs in West Africa in the Congo basin and is said to be common in connective tissue under the skin and in the eye. In the skin the worms produce Calabar swellings. *Onchocerca volvulus* is found in West Africa and South America and produces nodules in the skin with xeroderma, a form of lichenoid dermatitis associated with intense pruritus. The other known species of Filarioidea do not apparently appear in the skin or subcutaneous tissues in the adult stage. A small nodule with erythema and a mild degree of itching comparable to some extent with Calabar swelling and pruritus were

associated with the presence of the worm in this case.

Mrs. H—, European, age 45, came to me at 9 p.m. one night early in September, saying that she felt a worm moving under the skin of her neck. She had an irregular erythematous patch on the right side of her neck at the level of the thyroid cartilage about one and a half inches square. Close examination revealed a pale vermiciform streak 1 mm. wide and 25 to 30 mm. long coiled in wide sweeps roughly in the shape of the figure 2 with smaller irregularities in the main curves. An advancing slightly knobbed end could be seen moving at a slow rate, sometimes retracting but generally going forward. The rate of movement was about two to three millimetres a minute. I observed it for about 20 minutes during which time the coils formed roughly the figure 3. When first seen the whole of the apparent portion was about 25 mm. in length and seemed to be just under the epidermis. In fact it struck me it was so superficial that a good blister might expose the whole worm. I did not attempt to remove the worm that night for several reasons. It lay over a comparatively extensive area in a lady's neck and seemed so fragile that it occurred to me the dissection might damage the worm resulting in inflammation and unsightly scarring. Moreover by the time I could get the necessary materials ready for an operation the worm had become less distinct. The patient did not seem to be much inconvenienced by it. She said she had a slight itching and a sensation of something creeping under the skin. I decided to await developments and asked her to see me again the next day. By this time the patch of erythema was much reduced and it was difficult to be certain that any part of the worm could be seen.

When I saw her again the next day the patch of redness was reduced to a small area about 20 mm. by 12 mm., raised about 2 to 3 mm. above the surface. There was no pain or any other sensation associated with it. I concluded that the worm had coiled itself into a resting stage comparable to that of *Loa loa* in a Calabar swelling or of *Onchocerca volvulus* in a nodule, and decided to excise the part completely with a view to securing the specimen. This was done on the 16th September and a clean wound which healed with a hardly-perceptible scar resulted, the final result being much better than would have been the case had I attempted to dissect out the worm when first seen.

The subcutaneous tissue and the dermis of the excised part were teased out with a pair of needles and a living worm which in the coiled state was calculated to be 90 mm. in length was removed and preserved in 10 per cent formalin. The worm has been studied by Dr. Maplestone at the Helminthological Research Laboratory, School of Tropical Medicine, Calcutta, and readers interested in its detailed morphology and the discussion of its generic classification will find a full account by him elsewhere in this issue. The original impression formed by me on clinical grounds and from a preliminary examination was that this worm is a *Loa*, but of a species hitherto unrecorded either from India or Africa. Sir J. N. Duggan who kindly loaned me another specimen removed from the same case and referred to later in this article regarded his specimen as *Loa loa*, but in a letter to me dated 8th September, 1937, he states that parasitologists in Bombay and Madras to whom he had shown his specimen were not convinced that it was *Loa loa*. Maplestone in his report confirms my views and considers it to be a new species, if not actually a new genus and has suggested placing it tentatively in the genus *Loa*.

Zanaty, A. F. (1937). *Lancet*, II, p. 958.

He has named it provisionally *Loa inquirenda* and I agree that this has been aptly done in view of the lack of information regarding the male and embryos.

About a fortnight previous to the events related above, this lady called me by phone about midnight for an irritation in her left eye which had worried her for ten days and had suddenly become worse. I was out at the time and she was advised to see Dr. Chitnis, assistant to Sir Jamshedji Duggan of the Cowasji Jehangir Hospital, Bombay. Dr. Chitnis saw her that night and prescribed some drops but next morning when he examined her again, he declared that he could see a worm under the conjunctiva. Under a local anæsthetic, what were believed to be two worms, one 30 mm. and one 55 to 60 mm. in length, were removed and preserved. These were later very kindly loaned to me by Sir J. N. Duggan for examination and Dr. Maplestone considers them to be not two worms but separate portions of a single specimen which must have been severed in the process of removal. Unfortunately, the anatomical details in these fragments were damaged and the tail was missing. Portions of the uterus and the ovary indicated that the specimen was a female.

Fifteen thick films of the patient's blood have been examined for microfilariæ but none were found. These films were taken at various times both by day and by night. The eosinophilia was 6 per cent.

I have a note about this patient made about three years ago. She came to me then, complaining that she had noticed or felt what seemed to be a worm crawling under the skin of the front part of the thigh. When I saw her I could make nothing of it and dismissed the condition as a swollen lymphatic and of no importance. She reminded me of the occurrence when I removed this specimen.

She had been in Madras for three or four months in each year in 1920, 1923 and 1932. She visited East Africa on a short trip in 1935 and stayed in Nairobi for ten days. She was in Malaya from 1924 to 1931 and has been in Bombay since 1933. The patient herself thinks she was infected in Calcutta a few years ago on a short visit. She distinctly remembers, and her husband confirms the incident, being bitten by a large darkish fly which drew blood from the calf of her leg.

About eight months ago a male European consulted me about a pale worm-like structure which was irritating him on the right side of the abdomen just below the ribs. It seemed to me to be a distended lymphatic about 1 mm. wide and about 30 mm. long. I examined several thick films of his blood for microfilariæ with negative results. In the light of the present experience it is within the bounds of possibility that it was a similar worm. He was very worried about the matter and was insistent that it

A NEW FILARIAL WORM FROM A HUMAN BEING

By P. A. MAPLESTONE, D.S.O., D.Sc., M.B., B.S., D.T.M.
(From the Helminthological Research Laboratory,
School of Tropical Medicine, Calcutta)

THE clinical account referring to these worms and the records in India of worms found under similar circumstances are given in the above case report by Dr. Rishworth so this note is confined to the description of the parasites.

Specimen 1.—This was removed from an eye by Sir J. N. Duggan of Bombay and was found to comprise two fragments of a female worm. One portion about 6.5 cm. in length was the anterior end and it was 0.54 to 0.58 mm. in diameter. The head is bluntly rounded and the mouth is an inconspicuous opening in the anterior end, not surrounded by lips or other structures. The head papillæ are small and indistinct but two sub-median papillæ and a larger lateral papilla (amphid) could be made out on each side, near the anterior extremity. Cervical papillæ and excretory pore could not be found. The œsophagus is 1.25 mm. in length and is indistinctly divided into two portions, the anterior portion being about 1/10 of the total length. It is surrounded about the middle by the nerve ring. The vulva opens about 2 mm. from the

(Continued from previous column)

was a worm. I sent the man to a colleague in Bombay for a second opinion and he succeeded in convincing him that it was a lymphatic and nothing to worry about. It disappeared in about ten days and the man has now returned to England.

The following clinical features appear to be worthy of note. The formation of a red nodule in the skin preceded by a patch of erythema and irritation. The absence of microfilariæ in the blood, and the ease with which its occurrence in the skin might be overlooked. This would be even more likely in a dark-skinned patient. The presence of a worm in the patient's eye undoubtedly contributed to the discovery and removal from the skin of a second specimen. In the absence of so certain a clue as to the true nature of the condition it is not unlikely that other appearances of the species in the skin might be overlooked. This has probably happened on two occasions with me and I have described the circumstances in some detail in the hope that other observers may be assisted in detecting worms in similar circumstances.

anterior end and the vagina runs directly towards the posterior from this opening. As the worm was cut and the body contents had for the most part escaped further description of the internal organs is not possible, except to say that even in the vagina no eggs or embryos were present but only granular cellular matter such as is seen in most nematode ovaries. The second fragment was 5 cm. in length cut transversely at both ends and almost empty of contents so no anatomical details could be observed. In correspondence sent with this worm there is a statement that when the pieces were examined soon after removal from the patient's eye cuticular bosses were seen. These could not be found when I examined the specimen: it is possible that the injury to the worm with the escape of the body contents and its subsequent flattening caused these cuticular knobs to disappear.

Specimen 2.—This specimen, removed by Rishworth from the side of the neck, is uninjured and hence can be more accurately described.

The worm is a female, 13-14 cm. in length and 0.6-0.64 mm. in greatest diameter. When first placed in the clearing fluid out of 70 per cent alcohol the head presented distinct 'shoulders' as shown in figure 1b, when the clearing fluid

Fig. 1a.

Fig. 1b.

Fig. 1a.—Anterior end showing papillae, anterior portion of oesophagus, and nerve ring.

Fig. 1b.—Anterior end to show contraction before clearing (diagrammatic).

had completely impregnated the worm the outlines of the cuticle and body tissue were parallel as seen in figures 1a and 2. The oesophagus is 1.16 mm. in length and the vulva opens 3.34 mm. from the anterior end of the worm. The vagina does not run straight backwards but after a short posteriorly-directed coil it turns forwards to the posterior end of the oesophagus where it again turns backwards and runs posteriorly for a distance of 6.6 mm. behind the vulva (figure 2) where it divides into the two uterine tubes. The uteri pursue a posterior parallel course, one or other branch exhibiting an occasional forward loop for a short distance. The final coils of the ovaries are near the posterior end of the worm but are at slightly different levels, the anterior one being 2.34 mm. from the tip of the tail and the posterior one 1.04 mm. from the same point. The ovaries only run about 1 mm. forwards from

their posterior turns and then turn backwards again for a shorter distance before turning again forwards and so on in a series of three or four coils each coil being slightly shorter than

Fig. 2.

Fig. 3.

Fig. 2.—Anterior end showing vulva and vagina.
Fig. 3.—Posterior end.

its immediate predecessor so that the termination of the ovaries is a kind of elongate whorl. The uteri and vagina contain cellular material similar to that seen in specimen 1, but there was no sign of eggs or embryos even as far forward as the level of the vulva to which point this material reached.

The tail is straight and bluntly rounded, without cuticular flaps or papillae and the anus opens almost at its tip. The cuticle is irregularly studded with bosses and there are fine transverse striations which are more distinct in the posterior third of the worm. Some groups of the cuticular bosses are very closely set and are unusually prominent giving the skin a remarkably rugose appearance, but it is considered that this is to some extent caused by shrinkage during fixation in cold formalin in which the worm was originally preserved, but some of the smaller bosses are undoubtedly natural structures.

Discussion

It seems probable that these two worms are of the same species because, apart from slight differences in some of the dimensions, all the comparable morphological characters are similar except the course of the vagina. In specimen 1 there is no loop and it runs directly back from the vulva, but the worm was cut across some distance further back and all the body fluids and a great part of the organs had escaped so it seems likely that this coil disappeared owing to the tendency of the body contents to escape through the cut end. Both specimens contained similar cellular material and no eggs or embryos.

SOME UNUSUAL JOINT LESIONS

By P. N. RAY, B.A., M.B., F.R.C.S. (Eng.)

Officiating Professor of Clinical and Operative Surgery,
and Surgeon to the Medical College Hospitals, Calcutta

THE study of unusual and interesting cases of articular ailments is not without its compensation. In many of these cases, the diagnosis is a matter of considerable difficulty and treatment protracted and laborious. The disability and impairment of function may be out of all proportion to the pathological lesion. Moreover, it is often necessary to supplement any operative procedure by a prolonged course of graduated remedial exercises or of physio-therapy. The management of such cases, therefore, requires considerable experience and judgment. It is

(Continued from previous page)

It seems probable that these worms are adult but unfertilized females through no males being present, a hypothesis that is borne out by the failure to find microfilariae in the blood after repeated examinations.

These worms are clearly different from *Wuchereria bancrofti*, the common filarial worm of man in India. There is only one other possibly similar worm present in man in India, this is the parent worm of *Mf. malayi*, but the adult has never yet been found, and unfortunately the absence of microfilariae in this case prevents this worm being identified with or distinguished from this unknown species.*

In some respects this worm is very like *Loa loa*, because the shape of the anterior end, the short œsophagus, the position of the vulva and the cuticular bosses are similar, but it differs from *L. loa* in being two or three times as long, in having a straight posterior extremity and the anal opening sub-terminal. The worm also differs even more distinctly from all other filarial worms of human beings that have been properly described so it is apparently a new species, if not a new genus.

On account of its close affinities with *L. loa* and the fact that it agrees in all available particulars with the generic definition of *Loa* given by Baylis and Daubney (1926) it is proposed to place it tentatively in this genus under the name *Loa inquirenda* thus indicating its doubtful position, which cannot be fully established until the male is found.

REFERENCE

Baylis, H. A., and Daubney, R. (1926). *A Synopsis of the Families and Genera of Nematoda*. The British Museum (Natural History), London.

*It is noticed that frequent references to this unknown worm are beginning to appear under the name *Filaria malayi*. This is unfortunate, because whatever the worm is, it is very unlikely to be a *Filaria* in the strict sense, so that when it is eventually found and described the alteration in its name will lead to similar confusion and possibly to similar opposition as that which occurred when the time-honoured *Filaria bancrofti* was changed to *Wuchereria bancrofti* under the rules of nomenclature.

hoped that the conditions described in this paper will be found of interest.

I. Internal derangement of the knee: intra-articular tibial spur or exostosis

Although much has been written on the subject of internal derangement and athletic injuries of the knee joint, yet the rarity of an intra-articular tibial spur or exostosis seems to warrant the recording of the following case:—

Case I.—The patient, a Bengali male, aged 30, complained of a painful weak knee. Five years ago the patient was injured while playing 'soccer'. He was confined to bed for a month and the condition was diagnosed and treated as a sprain of the knee joint. The joint had never been free from pain since the injury. Some months ago, he was again injured when alighting from a tram car. There was much swelling of the joint and the pain was most marked when he attempted to stretch the limb fully. There was never any locking of the joint, nor was there any history of venereal disease.

On examination, the right knee was found to be swollen and free fluid was present. There was marked tenderness over the lower attachment of the external lateral ligament. All movements were painful but full extension was extremely so. The range of active flexion was just over 90 degrees. A 15 degrees flexion of the knee relieved the pain when walking. There was marked wasting of the quadriceps muscles, especially of the vastus internus. The patient was a well-built athlete and his general health was excellent.

Skiagraphy.—In the lateral view a small spine-like projection was seen in the anterior part of the articular surface of the tibia (figure 1).

Although the diagnosis was clinched by the skiagraphy and confirmed by operation, the restoration of function was not immediate. The patient required a prolonged course of physio-therapy for the weakened quadriceps muscles. The causation of the exostosis or spur is not easily explained. It was possibly the result of a partial ossification of the anterior cruciate ligament after an incomplete rupture or avulsion. This ligament becomes tense during extension of the knee and it prevents over-extension. It is attached above to the posterior part of the inner aspect of the external femoral condyle, and below to the upper aspect of the tibia in front of the tibial spine, either in front of or just mesial to the anterior cornu of the external meniscus. It is therefore probable that as a result of the 'soccer' injury there was a partial tear or avulsion of the anterior cruciate ligament, which was involved in the formation of the exostosis. The cruciate ligaments are ruptured only by severe injury. With regard to the mechanism of the rupture of the anterior cruciate ligament, it may be pointed out that it is caused by forced hyperextension of the knee joint together with internal rotation of the tibia on the femur and usually with the tearing of the internal lateral ligament.

II. Arthralgia of the shoulder joint: diaphysial aclasia

Extra-articular exostoses may give rise to troublesome pain in a joint. The shoulder

possesses a lesser degree of stability and mechanical protection than any of the other large joints of the body. These anatomical considerations are of significance in the interpretation of the clinical features of affections of this joint. Arthralgia of the shoulder joint is seldom seen without some degree of limitation of movement. The following unusual case may be of interest:

Fig. 1.—Intra-articular tibial spur or exostosis. In the lateral view, a spine-like projection is seen in the anterior part of the articular surface of the tibia.

Case II.—A Bengali boy, aged about 12, complained of weakness and pain in his left shoulder joint. There was no history of injury or infection. On palpation some irregularity in the shaft of the humerus was noted. The range of movements was limited in every direction. On skiagraphy, the underlying condition was revealed as diaphysal aclasia or hereditary multiple exostoses (figure 2).

This condition is a congenital or inherited skeletal deformity, characterized by irregular cartilaginous development and ossification at the ends of long bones, giving rise to multiple exostosis. After ossification of the affected epiphysis no further growth occurs in the exostosis. In this case, there were multiple exostoses in other parts of the body. The treatment of this condition is generally unsatisfactory. Any large exostoses interfering with muscles or tendons may be removed but where bony deformity is well marked radical cure is not to be expected.

III. Chronic arthritis of the wrist joint : chronic bone abscess of the radius

Tuberculous lesions of bones and joints require no comment, but there is a group of obscure infective bone lesions, which present many difficulties. The so-called 'Brodie's abscess' belongs

Fig. 2.—Note the deformity of the upper end of the humerus and multiple exostoses. A case of diaphysal aclasia.

to this group. It is surprising how often chronic osteomyelitis may be completely missed or wrongly diagnosed. In this connection the following case is of interest:—

Case III.—A Bengali boy, aged 12, complained of a painful and swollen wrist. There was no history of injury or recent illness. The onset was gradual and for nearly two months he had an evening rise of temperature, not exceeding 100°F. On examination, there was much swelling of the right wrist and all movements were painful and limited. The maximum tenderness was located over the lower end of the radius. The general health of the boy was poor and he looked small for his age. On skiagraphy, an area of rarefaction was seen in the metaphysis of the radius. The epiphysal cartilage was widened and the epiphysis

showed well-marked irregularity. There was no obvious new bone formation or periosteal reaction (figure 3).

The diagnosis lay between (i) tuberculous disease of the bone, (ii) chronic bone abscess (subacute septic infection), and (iii) bone cyst. The limb was put up in a plaster casing for a

of osteosclerosis which is a characteristic feature in skiagraphy. In rare instances, this zone of sclerotic bone may be absent and may even show a degree of rarefaction, as in the present case, simulating a bone cyst or osteitis fibrosa cystica.

Fig. 3.—Note the area of rarefaction in the metaphysis. The epiphysial cartilage is widened and the epiphysis shows well-marked irregularity.

Fig. 4.—Coxa valga, following infantile paralysis.

period of eight weeks but there was no appreciable improvement. The cavity was therefore opened and well curetted. The curettage proved to be granulation tissue of chronic infection. The convalescence was rapid and uneventful. The so-called 'Brodie's abscess' is a localized form of osteomyelitis caused by a low-grade infection, commonly of staphylococcal origin. The infective area is usually surrounded by an area

IV. *Coxa valga*

Coxa valga is a rare deformity, in which there is an increase in the angle between the neck of the femur and its shaft. Consequently, the length of the limb may be increased. In coxa vara, on the contrary, the angle is diminished to a varying degree. The early manifestations of coxa valga are awkward gait and limping and thus it may be mistaken for tuberculous disease

of the hip joint or coxa vara. It is usually congenital in origin but it may follow infantile paralysis.

Case IV.—A Bengali boy, aged 4, was found to be suffering from talipes equino-varus and extensive wasting of muscles of the lower limbs. He was unable

Case V.—A Bengali boy, aged 10, was brought in for limping and awkwardness of gait. On examination, it was found that the thighs were outwardly rotated and abducted. There was a history of rickets in infancy and, in the opinion of the mother, he was a delicate child. The diagnosis was confirmed by skiagraphy (figure 5). With regard to treatment, the hip joints

Fig. 5. Coxa valga of congenital origin.

to stand or walk. There was a history of infantile paralysis in early infancy. Skiagraphy showed bilateral coxa valga (figure 4).

Fig. 6.—Antero-posterior view. Note disorganization of the metacarpophalangeal joint of the index finger, and osteosclerosis of shafts of the phalanges of the middle and ring fingers.

Coxa valga of congenital origin is generally unilateral but bilateral progressive lesions are by no means uncommon.

were manipulated under anaesthesia and immobilized in plaster in an attitude of adduction. The result was fairly satisfactory.

It is important to note that re-education of gait is a difficult process at all times. With children both patience and perseverance are needed. In paralytic cases the prognosis would be dependent upon the extent and nature of the paralysis.

V. Charcot's disease of a metacarpo-phalangeal joint

Charcot's disease of the hand is very uncommon. The following case is of interest not merely on account of its rarity but also because of the presence of osteosclerosis of the shaft of two other phalanges.

Case VI.—A Bengali male, aged 45 years, complained of a painless swelling over the root of the right index finger and loss of movement in the joint. There was no history of injury or gout. The onset was sudden and the duration three or four years. The patient admitted having syphilis about twenty years ago. On examination, there was an irregular swelling of the metacarpo-phalangeal joint of the right index finger, painless and without any tenderness. There was hardly any voluntary movement of the muscles. On passive movement a soft grating sound was elicited. There was no wasting of the thenar and hypothenar muscles and dissociated anaesthesia was absent. Pupils reacted to light equally, but the knee jerks were very sluggish on both sides. The Wassermann reaction was negative. No other joints were involved. On skiagraphy, the joint appeared to be disorganized with loss of cartilage and bone, of both the head of the metacarpus and the base of the first phalanx. The latter also showed generalized decalcification. The corresponding phalangeal bones of the middle and ring fingers showed osteosclerosis of the shafts (figures 6 and 7).

The large joints are more liable to be affected, the knee and the tarso-metatarsal joints being the most commonly involved in tabes and the shoulder in syringo-myelia. But in tabes even the smaller joints may be affected, as in this patient. Female tabetics appear to be relatively more liable than male patients to osteopathies and arthropathies. The exciting cause of a tabetic arthropathy is often some trivial traumatism, such as a sprain or strain in a joint, in which the sensation of pain is impaired or lost, hence the greater frequency of tabetic arthropathies in the lower limbs.

Fig. 7.—The lesions are shown in the lateral view.

The onset of symptoms is nearly always sudden, dramatic and painless. Sometimes the patient wakes up from sleep to find that a joint has become greatly swollen, flail or useless. Sometimes the changes follow a slight sprain. Occasionally, however, the onset may be insidious. The appearance of a Charcot's joint is generally an early manifestation and may be the first evidence of the existence of tabes. The other signs, such as the Argyll-Robertson pupil, loss of knee jerk, visceral crisis, ataxia, Romberg's sign, dysuria, etc., may follow later. There is often a firm oedema round the joint, which may extend for some distance above the limb. A crepitus may also be felt.

The prognosis varies greatly. In some cases, the swelling may gradually disappear after a few weeks. In others, it may remain stationary without either regression or progress. The diagnosis is usually readily made by the presence of other tabetic manifestations, by the painless sudden onset and the clinical and radiological characters of the swelling. The differentiation from syringo-myelic arthropathy is not usually difficult. The chief characteristics are (i) muscular atrophy, particularly of the thenar and hypothernar eminences, (ii) involvement of the whole limb, and (iii) dissociated anæsthesia.

EXPERIMENTS ON THE SPIRILLUM OF RAT-BITE FEVER

By B. M. DAS GUPTA

(From the School of Tropical Medicine, Calcutta)

KNOWLES, DAS GUPTA and SEN (1936) have observed that 15 of a batch of 31 white mice (*Mus musculus*) showed spontaneous infection with *Spirillum minus*. These mice were caged in cages of narrow meshed iron-netting. No rat could possibly get at the mice to bite them. On looking through the literature it is found that other workers such as Robertson (1930), McCluskie (1930), and lately Francis (1936) have also recorded the occurrence of natural infection in these animals. How does this dissemination take place? To throw some light on this problem some experiments were carried out.

Possibility of intra-uterine transmission of infection.

Experiment 1.—Two young mice born of an infected mother, which showed a moderately heavy infection before delivery, were killed a few hours after birth and their heart blood was searched, but no spirilla were detected in either.

(Continued from previous column)

Summary

Some unusual joint lesions are considered briefly in this paper.

(1) The presence of an intra-articular tibial spur or exostosis may give rise to a troublesome internal derangement of the knee. An instance of this rare condition is here recorded. The causation of the spur is not easily explained. It was probably due to a partial ossification of the anterior cruciate ligament after an incomplete rupture or avulsion.

(2) Arthralgia of the shoulder joint, associated with diaphysial aklasia, is rarely met with. A case is recorded.

(3) Chronic arthritis of the wrist joint may be due to a chronic bone abscess of the lower end of the radius. The abscess cavity is usually surrounded by an area of osteosclerosis. In rare instances, as in the case recorded, this zone of sclerotic bone may be absent and may even show a degree of rarefaction, simulating a bone cyst or osteitis fibrosa cystica. The so-called 'Brodie's abscess' is generally of staphylococcal origin.

(4) Coxa valga is a rare deformity, in which there is an increase in the angle between the neck of the femur and its shaft. Two cases are recorded, one of which was congenital while the other followed infantile paralysis.

(5) Charcot's disease of the hand is very uncommon. A case of Charcot's disease of a metacarpo-phalangeal joint is recorded. It had the additional unusual feature of being associated with osteosclerosis of the shaft of two other phalanges.

Besides, two mice inoculated with this material showed no evidence of infection.

Experiment 2.—The blood of six mice of one litter of an infected mother was examined 26 times from the 15th day of birth during a period of two months. The results were consistently negative. The mother and the offspring were caged together all the time.

Experiment 3.—The blood and peritoneal fluid of two six-weeks-old mice born of an infected mother were subjected to intensive search for spirilla with consistently negative results. But they were readily infected following an inoculation of the mother's blood, the spirilla appearing in the peritoneal fluid on the 4th day in one and on the 9th day in the other.

Possible spread of the infection by the ingestion of food contaminated with the urine of infected animals

Experiment 4.—Two clean mice were put together in a small cage for 42 days. The only food that was given to these animals consisted of a small piece of bread and a piece of carrot or sweet potato soaked in urine collected from a number of infected mice. No infection resulted.

Experiment 5.—One mouse was fed on 14 specimens of urine (introduced to the back of the throat with a capillary pipette) during a period of 22 days from five infected mice. The animal was then kept under observation for nearly two months (56 days). No spirilla were detected in the blood and peritoneal fluid which were examined 17 times during the period.

It may be noted in connection with these experiments that to obtain a small quantity of urine from a mouse is quite a simple matter. The technique consists in lightly pressing the lower abdomen when one or two pellets of faecal matter and a few drops of urine are invariably voided.

Transmission by coitus

Experiment 6.—Two adult mice of opposite sex were caged together for 40 days. The male harboured the specific parasite. The female was separated from its companion when it showed evidence of advanced pregnancy. It gave birth to five young, one of which was killed by the mother within a few hours of its birth. Neither did the mother nor the offspring take the infection.

Besides the foregoing transmission experiments, investigations were also carried out, from other aspects of the disease, in man and animals.

Tolerance to re-infection

To determine whether an attack of rat-bite fever confers any degree of immunity against further infection the following experiment was undertaken:—

Experiment 7.—A healthy volunteer was infected with a strain of *S. minus* spontaneously occurring in a white mouse. After he had three

bouts of fever, he was treated with arsphenamine therapy and he recovered. Two months later he was re-inoculated with the same strain which had been maintained in a young guinea-pig. No infection resulted. Eight months after the initial inoculation he was given an inoculation with the spirilla isolated from a wild rat without infection resulting.

Wassermann reaction in experimentally-infected human beings and guinea-pigs

Experiment 8.—In this investigation two human volunteers and four guinea-pigs were used. The blood of the volunteers who denied all history of syphilis was examined for Wassermann reaction. The results being negative, they were infected with *S. minus*, originally isolated from a human case and maintained by passage through white mice. When the infection was generalized in these individuals, as shown from the isolation of the specific parasite from the blood by animal inoculation, their blood was tested again, and gave absolutely negative reactions. The guinea-pigs were infected from one of the above cases. The blood of the guinea-pigs was examined before inoculation and after a well-established infection. Before inoculation the blood of three animals was negative and that of the fourth gave a doubtful reaction. After the infection the blood of all the four animals was definitely positive.

Prevalence of spirilla in the peritoneal fluid of mice

All observers who have studied this spirillum in laboratory animals agree that a white mouse is the most susceptible animal. Unfortunately, this animal, as mentioned above, is liable to spontaneous infection. It has, therefore, been suggested that, before a diagnostic inoculation for rat-bite fever, the blood of the mouse should be examined carefully to ensure that it is free

Blood smear of an infected mouse showing scanty spirilla. (Photomicrograph \times ca. 850.)

from natural infection. But owing to the fact that marked fluctuations in the number of the parasites occur in the blood from day to day, as first pointed out by Robertson (1930), one or two examinations of blood smears are useless. It was suggested to the writer by Prof. Schöffner

that in experimental leptospiral infection in guinea-pigs very scanty infection can be detected in the peritoneal fluid. It was, therefore, thought that similarly scanty infection of *S. minus* in a white mouse might be more easily detected in the peritoneal fluid than in the blood.

Smear of peritoneal fluid of the same mouse, showing a massive infection. (Photomicrograph \times ca. 850.)

Accordingly, a comparative study on the prevalence of spirilla in the blood and peritoneal fluid in the infected mice was made.

Experiment 9.—Four adult mice were infected from a wild rat harbouring the spirillum. The blood and peritoneal fluid of these mice were examined by dark-ground illumination on seven occasions in three and two occasions in one and the results are presented in the following table:—

Number of mouse	Date of examination	SPIRILLA IN	
		Blood	Peritoneal fluid
Mouse no. 1	21-6-37	Scanty	++
	5-7-37	"	+++
	17-7-37	"	+++
	20-7-37	+	+++
	22-7-37	+	+++
	1-8-37	Negative*	++
Mouse no. 2	12-7-37	Negative	+
	13-7-37	"	+
	15-7-37	"	+

* Negative implies failure to detect the spirillum in wet preparation examined for five minutes by dark-ground illumination.

† Only one spirillum seen in 5 minutes' search.

‡ The animal was found dead next morning. Autopsy showed hepatization of the bases of both lungs.

Discussion

Troisier and Clement (1922) noted the presence of the parasite (*S. minus*) in the blood of the offspring of infected mothers. Salimbeni and his associates (1925) favoured the view of the possibility of hereditary transmission. Lately Levaditi *et al.* (1934) have shown that *S. minus* in white mice can be transmitted from the mother to the offspring either *in utero* or by the ingestion of infected milk. With regard to the prevalence of the spirilla in the mammary glands of white mice, out of 18 lactating females 17 contained the organism, while the number of uterine infections in the same lot was 7 out of 15. On the other hand, Abe (1924), Worms (1926) and McDermott (1928) are inclined to believe that hereditary transmission does not occur. One of these observers (McDermott) ground up the tissue of a young mouse born of an infected mother and injected into a series of mice, but failed in each instance to obtain the infection. In this connection, three sets of experiments (experiments 1 to 3) were carried out by the writer; in no instance was any evidence of intra-uterine transmission of infection discovered.

With regard to the transmission by the ingestion of infected milk, the present author failed to confirm the findings of Levaditi *et al.* (1934) who have noted that the ingestion of infected milk is the most potent source of transmission of the infection.

Mooser (1925) noted an instance in which an infection in a rabbit was transmitted by coitus. In view of the experimental results (experiment 5) obtained by the writer it is doubtful whether this is a mode of infection in mice.

Tsuneoka (1917) has observed that the specific organism is found in the urine and the infection can be transmitted through this agency. The present writer has failed to produce infection in mice by feeding for weeks on urine or food contaminated with the urine of infected animals. Basu (quoted by Knowles and Das Gupta, 1928) and Arima (1933) failed to transmit the disease by the bites of the fleas which showed only gut infection for a short time after the infected feeds. It may be said therefore that the mode of the propagation of the disease in white mice still remains obscure.

The results of experiment 5 show that an individual who has recovered from an experimental rat-bite fever becomes absolutely refractory to further infection with the disease no matter whether the specific parasite is isolated from a naturally-infected mouse or from a human patient.

Conflicting results have been recorded by previous workers as regards Wassermann reaction in rat-bite fever. Arkin (1920) records a negative Wassermann reaction in his own case but states that Kunusaki found one positive case in five. Costa and Troisier (1918), Mauriac (1918), Caldwell and Templeton (1932) and Briggs (1922) have reported cases with positive

Wassermann reaction. Blum and Clément (1925) state that they found reports of 14 cases with positive and 12 with negative Wassermann reactions. They record an instance in which there was a negative reaction before and positive one after infection with rat-bite spirillum. In the light of the investigation carried out by the writer (experiment 6) there is no evidence at all that a rat-bite fever case in the absence of coincident syphilis gives a positive Wassermann reaction. But the guinea-pigs after an established infection with *S. minus* gave positive reactions.

Summary

Experimental rat-bite disease has been studied in man and laboratory animals. Litters born of infected mothers (mice) have proved negative for spirilla, nor did they show any evidence of immunity to infection with the disease. Infection could not be produced in mice by feeding them on urine of infected animals or food contaminated with it for weeks. Adult mice of opposite sex were caged together. The male harboured the specific parasite. Neither the female nor its offspring were found infected in spite of repeated and careful examinations.

Experimentally-infected human volunteers gave consistently negative Wassermann reaction, but the guinea-pigs infected from these individuals showed positive reactions. The blood of these animals (four in number) before infective inoculation was absolutely negative in three and doubtful in one. The circumstances in which this complement-fixing property is shown by the infected guinea-pigs are a subject for a biochemist to investigate.

A comparative study on the prevalence of the spirilla in the blood and peritoneal fluid of the infected mice showed that the number of the spirilla in the latter does not diminish to an appreciable extent till the animal dies of the disease or of some intercurrent infection; whereas it is subject to marked fluctuation from day to day in the blood from which the spirilla may even temporarily disappear altogether.

After an attack of experimentally-induced rat-bite fever, man proved absolutely refractory to further infection.

I wish to express my gratitude to Major S. D. S. Greval, M.D., I.M.S., for the Wassermann tests required for one of the above experiments.

the eye†; at the least, it is a persistent nuisance. It is a tiny blackish insect and in general anatomical structure resembles flies of the brachycerous type (see plates and diagrams).

Life history.—This has not, I believe, been completely observed or recorded. The span of life is not definitely known. In captivity eye-flies do not live more than 4 to 5 days. It is likely that the duration of developmental stages varies with temperature. The periods given below represent the averages of several breedings carried out under warm weather conditions. The males in nature preponderate to the extent of three or four to one female. The males can be readily distinguished from the females by the absence of an ovipositor.

The breeding place *par excellence* is moist mud, particularly that contaminated by decomposition of organic matter. The damp soiled earth around improperly kept pail latrines is a favourite breeding place; breeding has been found in badly-kept cattle stables and more frequently in connection with badly-kept and contaminated surface drains.

Flies are capable of laying about 40 to 50 eggs. Each ovarian tubule contains 2 or 3 follicles and there are about 8 to 9 tubules on each side. From one fly 46 almost mature eggs were dissected.

The eggs (see plate II) are creamy white in colour on the average 0.4 mm. in length, one end round, the other tapering. They are marked with longitudinal striations and are convex on one side and slightly concave on the other. When water is poured on mud containing the eggs they float up, but sink again after a few hours.

The larva (see plates and diagrams) is typically acephalous. It hatches out in three days. The posterior end is obliquely truncated. There are three larval instars; it is not yet definitely known when the first and second ecdyses take place. The larva when it comes out of the egg is extremely small and almost transparent. It has no anterior spiracular processes. It exhibits slight undulating movements. The cephalo-pharyngeal skeleton is present. It feeds voraciously on organic matter and soon increases in size. After the first ecdysis the larva loses its skin as well as the cephalo-pharyngeal sclerites. The larval stage lasts 4 to 5 days. In the last stage it becomes creamy white due to excessive development of the fat body. It has thirteen segments. Just behind the head on either side are the openings of the anterior spiracles. These are provided with five finger-like processes. The tracheæ are continued backward and on their way give off numerous branches. These end posteriorly

in the posterior spiracles. The posterior spiracles consist of two nodes one on each side just in front of the last segment. The tracheæ are carried through these nodes and end in a circular ring which is deeply pigmented. Above the ring there are two openings side by side and these are surmounted on the surface by a ring of very fine pigmented bristles.

The alimentary canal and the excretory system resemble those of other muscid larvæ.

External morphology of larva.—The 7th to the 12th segments bear locomotory pads. These are arranged in three rows—

- (i) central rows consisting of six pads,
- (ii) two paracentral rows also six in number,
- and (iii) two lateral rows are in pairs.

Anatomical details of *Siphunculina funicola* (eye-fly).

Two additional pairs are also present, one on the posterior side of the ventral surface of the last segment and two posterior to the anus.

Pupa.—Soon after the last moult the larva begins to turn brown at the anterior end and becomes sluggish. This brown pigmentation spreads to the hinder end and ultimately the whole becomes a light-brown pupa. At first light brown the pupa later becomes dark brown. It has also thirteen segments and the spiracles projecting. The pupal stage lasts about two days and the imago emerges through a transverse opening in the pupa case at the anterior end.

Habits.—These insects are apt to collect in very large numbers on hanging strings, blind cords or hanging electric light flexes and in cobwebs. A flex used by the flies in large numbers was painted with two per cent fluorescein solution. Next morning a search was made for fluorescein in gutters and similar places round about and was readily detected in several drains of the type described already, 100 yards or so away. It is clear that the flies go at least this distance for food and deposition of eggs.

The flies lay eggs in large numbers when kept in test-tubes. These eggs failed to hatch out within two months at laboratory temperature or even when incubated at body heat.

Cobwebs, etc., on which these flies rest were spattered with a whitish substance. No eggs were found in this substance.

When the female is about to lay eggs she becomes sluggish, continuously massages the abdomen with her hind legs, time after time protruding the ovipositor and widening its aperture with her proboscis. Ultimately, the eggs are delivered with some fluid.

Bacteriology.—The following organisms were isolated from a serum-agar slope on which eye-flies were allowed to crawl:—

- (1) *Staphylococcus aureus*.
- (2) Non-haemolytic streptococci.
- (3) Enterococci.
- (4) Diphtheroids.

The mould growing on the slope was *Mucor mucedo*.

I have not been able to isolate any flagellates from the malpighian tubules as yet. That these flies can give rise to and spread conjunctivitis is very probable.

MYELOID LEUKAEMIA TREATED BY DEEP X-RAY THERAPY

By S. M. K. MALLICK, M.B., M.R.C.S.,
M.R.C.P. (Lond.), D.P.H.

MAJOR, I.M.S.

SHUJAAT ALI, M.D., P.C.M.S.

and

BALDEV SINGH, M.B., M.R.C.P. (Lond.)

(Punjab Medical School, Amritsar)

THE problem of the leukæmias continues to be formidable in spite of some vigorous efforts to overcome it. Once the disease is diagnosed, it spells death for the patient, for the physician helplessness and in the end disappointment. However, in recent years a ray of hope has brightened the prospects of temporary alleviation by deep x-ray therapy in this disease. We choose to describe below a case of chronic myeloid leukæmia which has been very much benefited by this treatment.

Regarding the ætiology of the disease there is yet a good deal of controversy going on. Although there are many who attribute the disease to some infection and quote fowl leukæmia as an example of it, and although the virus theory still needs a lot of experimental work to be accepted or rejected, yet the majority agree that it is a neoplasm of reticulo-endothelial tissue in which, in the case of myeloid leukæmia, the myeloid tissues of the

(Continued from previous column)

I have seen eye-flies sucking serum not only from wounds on horses but also from wounds and ulcers on human beings. The jungles in Hyderabad (Deccan) abound with these insects and since the sylvan population suffer much from yaws, these flies may play some part in the dissemination of this disease.

Preventive measures

These flies used to abound in Hyderabad (Deccan). Since the anti-malarial measures were taken in hand, all gutters, drains, etc., have been continuously sprayed with 'Malarial' to destroy mosquito larvæ, and eye-flies have almost entirely disappeared. It appears that 'Malarial' not only destroyed the culicid larvæ but also the adult eye-flies and their larvæ.

My sincere thanks are due to Colonel J. Norman Walker, C.I.E., I.M.S., Director, Medical and Public Health Department, H. E. H. the Nizam's Government, whose keen interest, suggestions and assistance helped in this preliminary work. I also thank Doctor C. F. Chenoy, Deputy Director of Public Health, for his advice, Doctor M. Farooq, Chemical Examiner and Bacteriologist, for his assistance in the bacteriological work, Doctor A. Rahman, Professor of Physiology, Osmania Medical College, for taking the photographs and my colleagues for much assistance.

bone marrow become the seat of malignant change.

Whatever the origin of it, the disease is by no means uncommon in this country. Some of these cases are overlooked for a long time and are labelled as cases of chronic malaria with splenomegaly or confused with kala-azar where the latter disease is endemic.

Case report

Doctor A. R., aged nearly 35 years, well built, height 5 feet 10 inches, had a feeling of pain in the abdomen in April 1936. As he was constipated, he took a soap-and-water enema and after he had evacuated he noticed an enlargement of the spleen for the first time. It was nearly four fingers below the costal margin. This enlargement of the spleen was attributed to chronic malaria and he therefore began to take quinine and arsenic without any improvement. On the contrary he began to feel a little run down and had some disturbance of digestion.

By about 9th February, 1937, when the blood films were examined the diagnosis of chronic myeloid leukaemia was made. By this time the spleen was nearly nine fingers below the costal margin. The only point of interest in the past history was that he had hæmoptysis some 10 years ago. He was x-rayed then and it was suspected that he had a tuberculous lesion in the right lung. Subsequent to this diagnosis with rest and good food he always felt very fit.

After a preliminary complete blood examination, treatment was started on 10th February, 1937, according to the following technique:—

Exposure factors: K.V.P. = 200, M.A. = 4, filter 5 mm. aluminium; time five minutes, to make a quarter erythema dose: distance ten inches.

First exposure to back of spleen, 2nd—right groin, 3rd—left groin, 4th—back of neck, 5th—upper part of thorax, 6th—left shoulder, 7th—right shoulder, 8th—both feet, 9th—lower part of both legs, 10th—middle part of both legs, 11th—both knees, 12th—middle of left thigh, 13th—middle of right thigh, 14th—sacrum and lower lumbar vertebrae, 15th—lumbar and lower dorsal region. Except after the fifth and the subsequent six exposures when an interval of three days each time was given because the patient felt rather sick, the treatment was given daily.

Only at the first sitting was the spleen exposed (at another clinic), otherwise it was always the bones. Total and differential leucocytic count, made before the treatment was started, showed total leucocyte count 112,000 per c.mm., with differential leucocytic count giving nearly 90 per cent polymorphonuclears and 12 per cent myelocytes. Hæmoglobin percentage nearly 80 per cent and total red cell count 4,800,000 per c.mm. Wassermann reaction negative.

After the first five exposures the total count fell to 37,000 per c.mm., while the polymorphonuclears came down to 80 per cent with 2 per cent myelocytes. Total red cell count rose to 6 million whilst hæmoglobin remained steady. Three more counts have been done at about a month's interval after the completion of the course of treatment. The first examination showed 12,000 leucocytes with 70 per cent polymorphonuclears and no myelocytes. The second about the same and the third done at the end of June showed 11,000 leucocytes with occasional myelocytes. The spleen has steadily diminished in size and now nearly three months after the treatment is not palpable even after a deep breath. There has been a remarkable improvement in the appetite, energy and weight. The case is being watched closely and it will be seen how he progresses subsequently.

Discussion

There are two points at issue in this case. Firstly whether tuberculosis bears any relationship to this disease for it has been noticed more

than once that in some of these cases in whom an earlier tuberculous infection has been overcome by rest and treatment there is development of myeloid leukaemia later on. While Custer and Crocker (1932), after reviewing the literature on the subject, conclude that the occurrence of true leukaemoid condition caused by tuberculosis is yet to be confirmed by autopsy. Thomas Cherry (1933) presents very interesting experimental data by inoculating mice with minute doses of virulent tubercle bacilli and thereby producing definitely a leukaemic condition and neoplasm of the pylorus.

Secondly, as to how the beneficial effect in this case has been brought about only by exposure mainly of the bones. In a recent article by Napier, Sen Gupta and Chaudhuri (1937) on the treatment of this disease an explanation has been put forth to rationalize the treatment. In their cases only the splenic region was exposed. One of the theories put forth by them is 'That the destruction of the immature cells from the metastases in the spleen produces a lytic substance that destroys or depresses the growth of the metastases in all parts of the body'.

This theory is evidently untenable in the present case for the spleen has been exposed only once at the beginning of treatment. There are perhaps two explanations feasible for the good effect of the x-ray treatment of this disease.

1. That the x-ray exposure of bones directly affects the hæmopoietic tissue and thereby checks its malignant activity. This explains the benefit only in the present case, but fails to explain the achievements of other clinicians who have benefited their patients by either exposure of the spleen alone as Napier *et al.* have done or by exposure of the whole body, alternately ventral and dorsal sides, without specially taking up the bones or the splenic region. The right explanation may be that of Eugenio Milani (1931). His theory is that of leucocytic crisis, and has been further elaborated by Raphael Isaacs (1932) by his investigations on the maturing effect of x-rays on blood-forming cells.

Milani believes that though the reduction in the number of white cells is the most apparent phenomena, it is not the fundamental one in the mechanism of improvement. This destruction occurs in crisis analogous to that occurring in the spontaneous leucocytic crisis in all leukaemias, the difference being that in those which occur after treatment the x-rays provoke a leucocytic increase which in turn provokes the crisis of destruction. The author gives figures by taking daily white counts and proves how after a marked rise in leucocytes a sudden crisis, which greatly reduces the count, occurs.

Isaacs states that the effect of Roentgen irradiation, small or large, on developing cells

(Continued at foot of opposite page)

SOME RECENT ADVANCES IN SURGERY*

By J. B. HANCE, O.B.E., M.A., M.D. (Cantab.), F.R.C.S.E.
LIEUTENANT-COLONEL, I.M.S.
Bangalore

IN September 1930, the late Lord Moynihan of Leeds, when delivering the opening address of the academic year of one of the greater London medical schools, gave it as his considered opinion that the limits of surgery as an art had been reached, and that any further attempt to enlarge it would consist of what he termed 'operative indiscretions'. It is not for me to criticize the accuracy of the statement of Lord Moynihan as regards operative technique, but that this accuracy did not extend to pathology, or rather to the applications of pathology to surgical treatment, was dramatically emphasized by the publication in October 1930 by an American orthopaedic surgeon, Dr. Winnett Orr, of an unassuming little book, *The Treatment of Osteomyelitis*. I shall have occasion to refer to this subject more in detail a little later in this lecture. I merely mention it now as an instance of the fallibility even of the greatest scientists when dealing with those inexact sciences which make up the work of the medical profession.

A similar statement to that of Lord Moynihan was made in the late seventies of the last century and was almost immediately followed by the publication of the work of Lister, a work

*An address delivered before the South Indian Science Association, at Bangalore, on 5th January, 1937.

(Continued from previous page)

is always stimulation, the cells in the myeloblastic stage react by proliferation and multiplication and that of the myelocytic stage by rapidly going through all stages of maturation. Thus there is never any depression of bone marrow; the larger dose causes such a rapid rate of growth that the normal end is reached sooner and the cellular activity appears then to be depressed. The reduction in cell counts is due really to the natural death of mature cells which have achieved senility although this senility has been hastened by x-ray therapy. To summarize, therefore, the good effect of deep x-ray therapy is brought about by stimulation of leucocytic formation and their maturation which subsequently ends in complete destruction of the mature cells as it happens in the normal course of events.

We are indebted to Major N. A. Qureshie for the details of the x-ray treatment.

which, as you are aware, revolutionized the practice of surgery and brought within the successful orbit of the surgeon many diseases and parts of the body which previously had been considered as unsusceptible of surgical treatment.

Lister's work let loose a flood of surgical discoveries which extended throughout the last quarter of the nineteenth century and continued almost unabated till the outbreak of the last war. The experience gained by surgeons on active service provided material for a second and minor spate of advance in surgical technique which continued into the 1920's; and it is only within the last 7 or 8 years that this spate seems to be falling in volume and the waters, so to speak, to be settling, and the surgical profession to have leisure to stand still and take stock of its discoveries. This stock-taking process has been a marked feature of the last 7 or 8 years and it is on some aspects of its results that I propose, with your permission, to address you to-night.

The general tendency of surgery during the last 7 or 8 years has been in the direction of conservatism. Many surgical procedures which were in vogue 10 years ago are now considered, in the light of further experience, to be in the nature of 'operative indiscretions'; and the conservative treatment adopted by some of 'our fathers in surgery' both before and during the time of Lister is, in some cases, returning into vogue. But, whereas formerly they might be ascribed either to lack of operative courage or to an incomplete knowledge of the process concerned, their modern adoption has behind it the sanction of pathology, a science which has made strides as striking as those of operative surgery, and over an almost exactly parallel period of time. Particularly is this conservative tendency noticeable in the modern treatment of acute infections.

John Hunter in the seventeenth century enunciated the principle of the treatment of infections as 'Where there is pus let it out'; and this principle has governed, and generally successfully governed, the treatment of acute septic processes unchallenged until quite recently. In the early years of this century a distinguished German surgeon, Professor Bier, advocated a conservative attitude in dealing with acute infection, no matter in what tissue it was found. This teaching was expressed in the system of treatment of acute infections by passive congestion to which the name of 'Bier's treatment' was given; this received a great deal of attention in the early years of this century and, moreover, has undoubtedly done much to improve the results of the treatment of acute infections. It is to-day employed in these conditions even by champions of active interference, with the object of bringing the inflammatory process within easier reach of the knife of the surgeon; and therein, in my view, lies its greatest benefit.

More recently, however, a French professor, D'Herelle, has demonstrated that the bacteria which are the causes of many acute conditions are themselves subject to invasion by even more minute organisms which are known as the 'eaters of bacteria', or bacteriophages. As the infection progresses, and if the patient survives, the vigour and virulence of the invading bacterium progressively diminishes until it finally ceases; D'Herelle proved that in some instances, at any rate, the final extinction was due to the parasitic action upon the bacteria of the bacteriophages. Among the organisms in which D'Herelle established this phenomenon was *Staphylococcus aureus*, which is the common organism of septic processes. The modern tendency, therefore, is now in the treatment of such staphylococcal manifestations as boils and carbuncles, to apply a convenient and occlusive dressing and to rest the part while the bacteriophage is developing, and to abstain from operative and possibly mutilating measures. My own experience in this form of treatment, I must confess, has not been entirely happy. I find that the results are not on the whole as good as those of free incision and evacuation in conditions such as boils and abscesses; while in carbuncles the results of total excision of the infected area have been, in my experience, superior either to the old-fashioned crucial incision and removal of sloughs or to the attempt to produce the bacteriophage. At the same time, in common with the advocates of the conservative theory, my experience has been that occlusive, and especially hygroscopic, dressings will frequently abort an infection which in the old days would have been encouraged to 'point' by fomentations and have involved the use of the knife with its subsequent scarring, however slight. I suggest that the next 8 years will see probably a synthesis of the two measures—conservative treatment in so far as it is successful in aborting, and operative where this form of treatment has demonstrably failed.

In one form of acute inflammatory disease the last 7 years have seen an advance, to which, in my opinion, it is not inappropriate to apply the adjective 'revolutionary'. I refer to the treatment of osteomyelitis, or inflammation of bone, whether acute or chronic. Up till the latter half of the third decade of the present century, the recognized treatment for this distressing disease of childhood was freely to expose the affected bone, to remove not less than one-third of its circumference as far as the infection extends and irrigate lightly with antiseptic, to pack in antiseptic dressings and allow the wound subsequently to heal from the bottom by granulation. Apart from the deformity which this necessarily and frequently involves, anyone who remembers such cases in the children's wards, with the daily agonizing dressings, which frequently in the early stages necessitated an anæsthetic, and the drawn, pinched and frightened faces of the children concerned, will not need any further illustration

of the objections to such treatment. It was these considerations which moved the American surgeon, Dr. Winnett Orr, to make an extensive study of the disease, and the conclusions which he reached may briefly be summarized as follows :—

Osteomyelitis is primarily a disease caused by one organism, usually *Staphylococcus aureus*. The previously recognized method of treatment, while admittedly giving adequate drainage to the products of this infection, necessarily substituted a mixed infection with other organisms before the primary monorganismal infection was controlled. Even in these days of aseptic surgery, it is impossible to avoid conveying infection to an open wound in daily dressings. Dr. Winnett Orr considered that the undoubted toxæmia was due to this mixed infection; while the daily excruciating dressings were responsible for such damage to the nervous system and general health of the child, that only the assumed necessity justified them; and in many cases an original amputation would have been more merciful. The logical deduction which Dr. Winnett Orr reached was that the rational treatment of osteomyelitis should be to eliminate the infection if possible, and at all costs to avoid the mixed infection; and from this deduction developed the Winnett-Orr technique, which may briefly thus be described.

The affected bone is exposed as before throughout the extent of the infective process. Thereafter sufficient, but only sufficient, bone is removed to give adequate exit to the products of infection. Structures which are obviously already devitalized are removed and the cavity in the bone is lightly cleaned so as to avoid damage to such of the bone-forming cells and blood vessels as have survived the infection. The wound is thereafter swabbed out with a 10 per cent solution of iodine in rectified spirit, and the excess of this solution is removed with absolute alcohol. Thereafter sterile autoclaved paraffin is poured into the cavity which is moreover lightly packed to the surface with sterile gauze well-soaked in the paraffin. Sterile paraffin-soaked dressings are applied over the wound with sterile cotton-wool, in the ordinary way. The limb is then immobilized in plaster of Paris, *no window being left*, and the plaster extending sufficiently to immobilize the joint above and the joint below.

Dr. Winnett Orr claims that, provided adequate bone technique be observed during this operation, mixed infection is avoided and the original infection if not eliminated is, at any rate, greatly attenuated. The subsequent process of granulation goes on freely and undisturbed under a protective coating of paraffin, while the absorbent dressings absorb the discharges, which, if not sterile, are of an extremely lowered virulence. Nothing short of a grave constitutional disturbance, in Dr. Winnett Orr's opinion, justifies the opening of the plaster under three weeks; and when its opening is carried out, it is found that

the granulations, when the discharges have been washed away with sterile saline, are healthy, vigorous and, above all, insensitive. The original steps, including and subsequent to the application of iodine, are repeated and the part again replastered.

The same principles are followed in the treatment of chronic osteomyelitis, *i.e.*, when mixed infection has been established by the bursting of the abscess to the exterior with subsequent necessary dressings. In these cases a greater or less proportion of the bone concerned has been killed and forms what is known as the sequestrum, while the defensive reaction of the body and notably of the periosteum has thrown down round it an envelope of new bone known as the involucrum. The sinus communicates with the exterior through a hole in the involucrum which is known as the cloaca. In dealing with such cases the Winnett-Orr technique differs only in degree. Nature has limited the infective process to the cavity of the involucrum. This, therefore, is laid open and the dead bone or sequestrum removed and the cavity thereafter is treated exactly as that produced in the acute infection by the interference of the surgeon.

When, in October 1930, I saw this system of treatment carried out at the Bristol General Hospital, my comment to myself at the time was that 'this is murder'! I followed that case through, and as a result, I have committed well over 200 such 'murders' since, varying from the complete removal of the diaphysis of the ulna to the partial removal of the os calcis. I have lost two cases: one from tetanus, presumably due to the survival of spores in the paraffin which in the earlier cases I used sterilized in boiling water but not autoclaved; and one debilitated child with chronic osteomyelitis, who caused the anaesthetist grave anxiety during the operation and died from delayed shock. Of the other cases I would only say that so far from having no cause to regret this treatment, each successive case makes me its more enthusiastic champion. The average number of dressings in an ordinary case of sequestrotomy by this technique is 4, at three weekly intervals. When the patient finds that the first dressing is painless, his fear is abolished; whereas from the moment the treatment is adopted the pinched toxic look is replaced by one of well-being which is a contrast as dramatic as it is satisfactory.

You will naturally say that this description is too enthusiastic and that there must be some snags. There are. Contrary to the recorded opinion of Dr. Winnett Orr, these cases smell, and smell abominably; and it is essential, at any rate during the earlier stages, that they be treated on the verandah. This is the only drawback to the treatment of which I am aware; but it is a serious drawback as any member of my nursing staff will tell you.

Peritonitis.—Another instance of conservative trend in modern surgery is in the treatment of diffuse peritonitis or of the paralytic distension

of the bowel which follows extensive intra-abdominal operations, and which may persist in cases of intestinal obstruction after the mechanical obstruction has been relieved by operation.

Modern opinion supported by pathology has reverted to the main principles of the technique of 50 years ago, supported by the additional appliances which development has placed in our hands. The injections of drugs to stimulate the parietic intestinal muscles have proved unsatisfactory, and they have now been largely replaced by allowing the muscles to rest while guarding against distension and supporting the body fluids. The modern treatment of this condition is the drainage of the intestine by the in-dwelling duodenal tube, to preclude distension of the stomach, the administration of intravenous saline and glucose by the continuous drip method, thereby replacing the lost body fluids and chlorides and supplying the liver with an assimilable form of nourishment, guarding against restlessness by injections of morphine, and relieving pain by hot fomentations to the abdomen, and leaving the bowels to act in their own good time.

Another and more recent suggestion, which is fascinating in theory and deserving of a very thorough trial, is to combine this treatment with inhalation of almost pure oxygen. It is known that the cause of death in paralytic ileus is the absorption of the toxins produced in the paralysed loops of the gut by the multiplication of anaerobic organisms. These organisms are normally inhabitants of the large intestine, and can only develop in the small intestine in the presence of stasis of its contents and in the absence of oxygen. The theory of oxygen inhalation, therefore, is that by inhaling pure oxygen the partial pressure of the gas in the alveoli of the lungs is raised; and therefore the partial pressure in the systemic circulation, including that which nourishes the parietic loops of the bowel, is also similarly raised. This increase in the oxygen supply to the gut is supposed to inhibit the development of anaerobic organisms and prevent the elaboration of their toxins. If I may be pardoned a personal note in a general survey, I would suggest that the application of this technique in 'Ragi' obstruction be given an extended trial. My own results in three cases have been very encouraging.

Burns.—The treatment of burns has been improved out of all recognition in the last 7 years by the introduction of the use of tannic acid. Prior to the use of this drug, the treatment of burns was unsatisfactory in the extreme. The shock of the burn itself, the toxæmia from the inevitable mixed infection during the long drawn out dressings, and, when healing had taken place, the contractions of the scars involved, all combined to make the immediate mortality of the condition high, and the ultimate results unsatisfactory, from mutilation.

With the introduction of tannic acid which originally was sprayed upon the burnt area,

after a thorough cleansing under an anæsthetic with antiseptics, and which produced an extensive coagulum over the whole burnt area beneath which healing rapidly took place, the immediate improvement in the treatment of burns was extremely dramatic. But there still remained a certain proportion of cases in which, for various reasons, the coagulum failed to 'take', either wholly or in part. The secretions accumulating underneath it tended to separate the coagulum from the underlying tissues; and imperfect cleansing permitted sepsis to go on, with the result that a greater or lesser amount of blistering occurred and allowed the septic process in some cases to continue. Experience has proved that the combination of antiseptics, such as Dettol, with the tannic solution has tended to obviate these causes of failure. In many cases where spraying alone is unsuccessful, the removal of the blisters and the application to the denuded area of fomentations of a strong solution of tannic acid with antiseptic will induce coagulation in the areas concerned. The net result of the tannic acid treatment of burns has been to reduce the immediate mortality in a very marked degree, and almost completely to obviate, on the one hand the necessity for skin grafting, and on the other hand the contractions which so frequently follow healing.

Fracture.—In the West, the treatment of fractures has also made remarkable strides during the last few years. The use of the portable x-ray apparatus in controlling the reduction of the fracture and the formation, in most large hospitals, of fracture clinics have combined to ensure accurate reduction and intelligent and thorough after treatment. The latter has been further facilitated by the use of the unpadded plaster cast after reduction, according to the teaching of the distinguished Austrian orthopædic surgeon, Dr. Böhler. With the perfection of these methods the operative reduction of fractures in which I was trained by Sir Arbuthnot Lane is increasingly receding, in the opinion of most surgeons, into the realm of 'operative indiscretions'. While this may be a subject for regret to the lover of artistic operative technique, there can be no question that it makes for the general good of the public. The technique of bone surgery as enunciated by Sir Arbuthnot Lane is both meticulous and difficult of achievement, but it is absolutely essential to success. Sir Arbuthnot Lane stated that the only reason for a failure in bone operations was 'dirty surgery', and thereby stated a profound, if unpalatable, truth. If, therefore, equally good results can be obtained by methods which do not impose such restrictions upon the surgeon, it follows that a much greater measure of success will be obtained. Moreover, ample scope for artistic and specialized operating remains to the orthopædic surgeon in those cases in which, for various reasons, the union is either faulty or absent after reduction and treatment by conservative measures. In such

cases the drill, steel plates, and screws of Sir Arbuthnot Lane have been mostly replaced by the 'bevelled bone craft'. A large number of ingenious instruments has been invented for the purpose, but the fact remains that an orthopædic surgeon may take as much pride in a well-fitting and successful bevel-graft as may the expert cabinet maker in a beautiful dovetail.

Peptic ulcer.—This disease still, unfortunately, remains a field of battle between the physician and the surgeon; but as the years pass by there is evidence that a peace which is honourable to both sides and beneficial to humanity at large is drawing nearer. We are to-day concerned with the surgical aspect of this disease; and this must necessarily vary with the point of view of the individual surgeon. I may, therefore, perhaps be excused if I venture to summarize the subject according to my personal convictions, which are briefly as follows:—

Subject to certain exceptions, to which I shall refer later, peptic ulcer is, in my opinion, primarily a medical disease. Whatever be its causation (and there are many theories in the field) one factor is almost invariable; and that factor is the excess of acidity in the gastric juice. In the vast majority of early cases, if the excess of acidity can be controlled by medical means the peptic ulcer will heal and the symptoms disappear. It then becomes incumbent on the patient to continue medical treatment of the condition indefinitely. Only when such treatment has demonstrably failed, or when complications (constituting the exceptions which I shall propound) have occurred, does the condition come within the realm of the surgeon.

The exceptions which, apart from failure of medical treatment, dictate surgery may be summarized as severe hæmorrhage, perforation, or the suspected onset of malignant change in the ulcer. This latter applies exclusively to gastric ulcers, since carcinoma of the duodenum is so rare as to constitute a pathological curiosity. To these exceptions I would add the occurrence of a peptic ulcer in an Indian patient of the uneducated peasant class in whom the maintenance of dietary restrictions after medical treatment is, if not impossible, at least very improbable. Assuming that such conditions have arisen as dictate surgery, what is the modern opinion as to the operation of choice?

The operation of gastro-jejunostomy devised and perfected by Lord Moynihan is falling into disrepute. For this, neither the operation nor its originator can be held justly to blame, but rather the indiscriminate use—or misuse—of the measure after imperfect investigation. As we are all aware, the operation consists in making a short circuit between the pyloric end of the stomach and the upper end of the jejunum to encourage the acid products of gastric digestion to pass directly into the small intestine without traversing and irritating the duodenal ulcer. In practice, this is only partially obtained unless

the pylorus is at the same time closed; and one-way traffic is the exception after this operation. Further, the operation does nothing in itself to lessen the excessive production of acid by the stomach cells. As a result, unless it is performed in carefully selected cases, not only does the immediate result desired, *i.e.*, the healing of the duodenal ulcer, not take place but an added complication may, and frequently does, arise in ulceration at the stoma, in consequence of undiminished acidity in the gastric juice and imperfect healing at the site of anastomosis. This complication which is becoming, unfortunately, increasingly common, is one of the most devastating conditions that either physician or surgeon can have to treat. The operation of gastro-jejunostomy, therefore, should, in my opinion, never be performed in the presence of high gastric acidity, and it should also never be performed for the relief of duodenal ulcer unless there be at the same time stenosis of the pylorus with marked gastric delay. For the latter condition, produced by the scarring of a long-standing chronic pyloric or duodenal ulcer, gastro-jejunostomy is still not only justifiable but also successful.

Modern researches into gastric digestion have shown two salient facts; the first is that acidity is produced entirely by the cells in the fundus of the stomach and in its body; the normal secretion of the pyloric antrum is alkaline in reaction. Moreover the cells of the pyloric antrum not only produce the chemical stimulus to the secretion of the digestive juices, gastro-secretion, but also produce the as yet unisolated anti-anæmic factor, which is supposed to activate the liver and to guard, in the healthy body, against the development of Addison's anæmia. It follows, therefore, that for the cure of peptic ulcer the ideal operation should diminish the secretion of gastric acidity, either remove the ulcer concerned, or establish conditions which allow of healing, and preserve the functions of the pyloric end of the stomach. This 'physiological' operation has, in fact, been devised by the distinguished Austrian surgeon, Finsterer, and is receiving increasing notice from surgeons in other countries, notably Ogilvie in London, and Somervell and Orr in India.

As we are aware, 90 per cent of gastric ulcers occur at the lesser curvature proximal to the pyloric antrum. Finsterer's operation may, therefore, be summarized as the removal of as much as possible of this ulcer-bearing acid-secreting portion of the stomach, leaving only the fundus. The occlusion of the pyloric antrum of the stomach leaves the pylorus open to receive its alkaline secretion; and the establishing of a small stoma between the jejunum and the remainder of the stomach in such a fashion as to constitute an amended lesser curvature or 'gastric pathway', permits of maceration and digestion of the stomach contents, and allows of a modified gastric digestion by what remains of the acid-pepsin in the gastric juice.

This then is I think now generally accepted to be the ideal operation for peptic ulcer, whether it be gastric or duodenal, which demands surgical interference. It is a procedure not unattended with operative and technical difficulties; and therefore its importance, in cases of mechanical obstruction and normal acidity, is not to be considered as superior to that of the simpler gastro-enterostomy, which, indeed, should be reserved for these cases and these cases only.

Other regions.—Space only permits of brief reference to other notable surgical advances. The work of Chevalier Jackson in America and of Tudor Edwards in London has opened up a wide field of useful surgery in the thorax. The improved methods of diagnosis elaborated by the former have permitted cancer of the lung to be diagnosed in its early stages and have brought the condition within the successful orbit of the surgeon. Ten years ago the excision of the whole or part of the lobe of a lung would certainly have been considered an 'operative indiscretion'; but nowadays, with intra-tracheal anaesthesia, the operation is, in the hands of a skilled and specially trained surgeon, hardly more dangerous than that for the removal of a kidney. Partial or total lobectomy is increasingly practised for such conditions as persistent abscess of the lung, for persistence of the bronchiectatic cavity, and for the removal of an early carcinoma. The results are most satisfactory; and one feels that in chest surgery lies the refutation of the statement by Lord Moynihan to which I referred at the opening of this lecture.

So far, unfortunately, the oesophagus has largely defeated the surgeon. I believe that in the history of surgery only three operations for the removal of cancer of the gullet and for its reconstruction have been successful. It was my privilege to be present at an extremely gallant and skilful attempt in this direction by Mr. Gordon Taylor of the Middlesex Hospital, which would undoubtedly have added to the number of successes had not that dreaded complication, pneumonia, supervened on the 10th day.

As regards surgery of the vascular system, the successful surgical treatment of aneurysm has long been in vogue in America, and to a lesser extent in Europe. A recent life-saving advance in the surgery of the arteries has occurred in the localization of embolism of the main arteries, and the removal of the clot before gangrene has had time to set in in the parts supplied. This operation has been performed, with notable success and increasing frequency, in cases of embolism of the main vessels of the limbs (usually at the elbow or behind the knee).

The surgery of the autonomic nervous system has proved disappointing. Some years ago it

MANAGEMENT OF HEAD INJURY CASES IN RURAL PRACTICE

By P. C. DUTTA, M.B. (Cal.), F.R.C.S. (Edin.)

CAPTAIN, I.M.S.

Civil Surgeon, Sargodha, Shahpur

The medico-legal case

THE rural practitioner generally feels helpless when a case of head injury arrives. He should realize that he can do quite a lot for the patient and often the life of the latter will depend on his careful judgment and management of the case. Serious operative treatment gives good results only in expert hands, in specially equipped hospitals, otherwise the treatment is more or less the same for every practitioner and dispensary, and therefore the rural

(Continued from previous page)

was considered that in the division of the post-ganglionic fibres of autonomic nerves supplying blood vessels, lay the successful treatment of the spastic conditions of the arteries, of the limb muscles, or of senile gangrene from arteriosclerosis. These fibres, which are constrictor in function, being paralysed it was considered that passive dilatation of the arteries would overcome or mitigate the condition. The operation is one of considerable technical difficulty; and its results in the main are not very superior to the simpler operation of the division of these fibres in the outer coats of the arteries concerned. In other words, lumbar sympathectomy has few, if any, ultimate advantages over peri-arterial sympathectomy, and, as such, is receding into our increasing category of 'operative indiscretions'. In two conditions, however, the surgery of the sympathetic nervous system is still not only justifiable, but successful. In the treatment of that rare disease of childhood, Hirschsprung's disease or megacolon, the division of the post-ganglionic fibres running along the course of the inferior mesenteric artery and supplying the constrictor muscles of the large intestine is brilliantly successful. The other condition in which sympathetic surgery is attended with satisfactory results is the excision of the pre-sacral plexus in cases of inoperable carcinoma of the uterus, prostate, or rectum, where this operation is followed by a marked relief of the agonizing pains which occur in the later stages of these fatal diseases.

Conclusion.—And that brings to end this very incomplete survey of some of the recent advances in surgery. I shall in conclusion quote the summary of the subject by one of the greatest living surgeons in the English-speaking world—Sir David Wilkie of Edinburgh:

'The surgeon requires an ever-broadening basis of education if his practice is to keep pace with the advances and assimilate the fruits of medical science. The gap between medicine and surgery is narrowing and the operating physician is coming into his own'.

practitioner is not very unfavourably handicapped in the matter.

Before going into the treatment, I will discuss one or two medico-legal points which often confuse the rural practitioner.

In rural practice the injury is usually the result of a fight. Therefore to assess the degree of damage, the medical officer must examine every case very thoroughly before giving a certificate. Generally the injured person will feign to be much more seriously ill than he really is, and so the practitioner must depend more on physical signs than symptoms and in very few conditions is he in a position to gauge the exact nature and degree of the lesion as in head injury, from the physical signs.

Recently I saw a case which was diagnosed as a 'simple' injury by a medical officer. The patient walked into the dispensary, was quite conscious, and more or less normal except for a lacerated wound in the head and a black eye, so the doctor did not examine the case as thoroughly as he would have done otherwise. On further examination it was revealed that he had hæmoptysis, unequal and sluggish pupils, pulse 64, and the cerebro-spinal fluid (on lumbar puncture) was mixed with blood. He obviously relied more on the symptoms, but after full examination there was no doubt that it was a case of 'grievous hurt' if not a dangerous injury.

In some cases the patient will try to belittle the seriousness of the injury for some reason or other. Generally, there is some motive behind it and unless the doctor makes a careful examination, he may be involved in serious trouble. In one case where a person was very badly beaten, the doctor did not report the matter to the police, as he did not consider the case to be serious enough. The injured person also requested him not to report it to the police. The motive of the patient is difficult to understand in such a case. It may be that he wanted to take the revenge himself and a police record would have gone against him in that case. However, the person died on the second night after the injury, and in his judgment the judge passed an injunction on the conduct of the doctor. The doctor's statement was that he did not consider the case to be serious enough. In my opinion he can only be blamed if he did not make a thorough examination, which he stated he did. So in these cases it will be wise for rural practitioners to record the negative evidence as well in the case sheet, at least for his own protection.

From these two examples it is evident that no reliance can be placed on the patient's statement or appearance. The patient in an average medico-legal case will try to hoodwink the doctor by feigning to be more seriously ill than he really is and the attending physician must rely on the actual physical signs present and must record them, not only for evidence, but also for assessing the progress and guidance

for further treatment. For this reason a record of negative findings is no less important than positive ones.

Classification of head injuries.—Injury of the head may cause the following lesions, either singly or in combination :—

1. Simple scalp wound.
2. Simple fracture of vault.
3. Fracture of the base.
4. Concussion.
5. Cerebral compression.
6. Cerebral laceration.

Investigation of a case of head injury

As soon as a case of head injury arrives, an attempt must be made to find out the exact nature and degree of damage sustained by the skull and its contents.

I. Preliminary examination

1. Obtain a careful history.

The exact nature of the fall or violence must be enquired into and the sequence of events that followed immediately subsequent to the injury should be noted. The period of unconsciousness following the injury is important; whether there was the temporary disturbance of slight concussion, a brief loss of consciousness followed by rapid return to consciousness; or deep unconsciousness of a severe concussion; or yet again the consciousness which is retained for some time after the accident, but presently followed by a state of stupor. The third denotes cerebral compression.

2. Is shock present, and if so to what degree?

Shock is an inevitable accompaniment of concussion and actually there is no clear line of distinction between the two. For the moment, the occurrence of shock is not without advantage, for on account of the associated lowering of intra-cranial pressure, through reduction of general blood pressure, it affords temporarily a safeguard against bleeding immediately after the accident. So although the shock should be treated, none of the intensive stimulating methods should be employed.

3. Examination of the local part.

The wound in the scalp and the amount of damage to the skull are noted. If there is any depression, its nature and degree are also noted.

4. The whole body should then be carefully examined to find out if any other injury is present.

II. Detailed examination to assess the degree of cerebral damage

This must be recorded.

1. Is the patient unconscious?

When the patient is unconscious, begin the investigation by estimating the depth of unconsciousness. This is a reliable index of the degree of intra-cranial damage and provides a standard by which we can contrast further

improvement or deterioration. Four tests are applied in the following order :—

(i) A simple question such as 'What is your name', spoken in the ordinary tone of voice.

(ii) An imperative question spoken loudly close to the ear as 'Raise your hand' or 'left foot'.

(iii) Induction of a painful stimulus by pressing the finger nail against the supra-orbital notch.

(iv) Testing the corneal reflex.

Response to the first indicates comparatively slight concussion, while failure to react to the last shows the deepest degree of unconsciousness compatible with life.

2. Pulse.

Quick pulse of small volume is the usual accompaniment of concussion, but in the absence of complications, it soon returns to normal.

A slowing pulse rate accompanied by increased volume is a hint that compression is developing.

A quick pulse rate maintained at high speed and yet showing increased volume is an indication that some degree of cerebral irritation without localized compression exists.

3. Respiration.

Changes in respiration are less constant, but they too are important.

In concussion, respiration is slow and shallow. Irregularity of respiration and particularly Cheyne-Stokes' breathing indicates increased intra-cranial pressure.

A much quickened respiration points to serious cerebral laceration, generally of a diffuse character.

In advanced cerebral compression there is irregular stertorous breathing which indicates increasing bulbar compression and failure of the vital nuclei in the medulla.

4. Pupil.

As a general rule, pupils are moderately contracted and react sluggishly to light.

Inequality or asymmetry of the pupils indicates cerebral lesion and any further change in them will indicate that the lesion is still progressing. Thus inequality in the earlier stages is due to contraction of the pupil on the same side as the lesion (due to irritation), while on further compression, it is dilated on the same side as the lesion and contracted on the opposite side, and on still further compression both are dilated.

If one pupil is widely dilated and fails to react to light, the other presenting a normal appearance and retaining light reaction and this is noted comparatively suddenly in the progress of the case, one or other of two explanations is likely, a pontine hæmorrhage or œdema, or cerebral compression developing on the same side as the dilated pupil. The latter is of significance in the recognition of compression syndrome.

5. Temperature.

Assuming that extra-cerebral causes have been excluded, a rising temperature means that there is some degree of cerebral damage.

Uncomplicated concussion does not exhibit pyrexia.

Few individual features are more suggestive than pyrexia, and in general it may be stated that the earlier the manifestation and the more intense the pyrexia, the more serious the cerebral damage.

6. Bleeding from the ear, nose, or throat.

If blood is escaping from the ear, its character should be noted; if the consistency is more watery than normal or coagulation is delayed, the probability is that cerebro-spinal fluid is mixed with it.

7. Blood pressure.

This must be recorded at two-hourly intervals for 24 hours.

Immediately after the injury, the blood pressure falls and as recovery advances, it rises. If it does so gradually, and after rising a few points above normal readjusts itself to average figure, prognosis is good.

If after the preliminary fall, it rises to a high level and is maintained, it indicates increased intra-cranial pressure.

On the other hand, in very severe injuries, as associated with extensive fractures of the skull, the blood pressure may remain low for the entire period of the illness.

8. Paralysis, twitching and convulsion.

Any evidence of twitching is noted, and the limbs are moved in various positions in order to ascertain if there is any flaccidity or spasticity.

9. Escape of cerebro-spinal fluid from the wound or ear.

10. Reflexes.

The tendon, plantar and abdominal reflexes are examined, but their evidence is not particularly trustworthy in head injury.

III. Clinical features of cerebral damage

A. Concussion.

B. Compression.

C. Laceration.

A. Concussion

The clinical appearance resembles that of surgical shock with the addition of disturbance of consciousness in a varying degree. The patient may be unconscious to the first or second degree, pulse quick and of reduced volume, respiration quick and shallow, blood pressure reduced, temperature subnormal, muscles flaccid, appreciation of pain diminished, skin pale and surface temperature lowered.

B. Compression

1. Due to cerebral oedema. It is due to the local oedema which follows on every injury of

the brain. After about 24 to 48 hours, the patient passes into an exaggerated state of reaction, he lies curled up in bed, face buried under the bed clothes and resists all forms of interference, specially exposure to light, and complains of severe headache. Temperature is raised, face flushed, pulse full and slow.

2. Due to intra-cranial hæmorrhage.

Remembering that concussion almost always follows immediately after a severe head injury, it is obvious that a latent period must follow before the symptoms of intra-cranial hæmorrhage can develop. In extra-dural hæmorrhage the symptoms may appear in a few hours, but in sub-dural hæmorrhage it may take several days.

In extra-dural hæmorrhage a period of remission generally intervenes between the concussion which immediately follows the injury and the compression to which the hæmorrhage gives rise. In this period the patient may recover consciousness and there may be a lucid interval of perhaps a few hours. During this period the blood pressure is steadily rising, the patient begins to complain of increasing headache, then he becomes irritable and later drowsy and finally comatose with stertorous breathing, flushed face, and slow, full pulse. There may be hemiplegia on the opposite side of the body with rigidity and possibly Jacksonian convulsions in the early stages. Later on, rigidity may appear on the same side as the lesion from generalized compression and, unless its true nature is recognized, it may lead to erroneous diagnosis of the side of hæmorrhage. Pupillary changes have already been described. Still later, the medullary centres become paralysed, the pulse becomes rapid, weak and irregular, and the respirations uncertain and gasping; these indicate that the terminal stage is fast approaching.

In the more serious cases the stupor of concussion passes almost imperceptibly into unconsciousness of compression, and unless a very careful watch is kept, the opportunity of affording relief may pass before the condition is diagnosed.

The other and the most important sign of increased intra-cranial pressure is the increased tension of the cerebro-spinal fluid. So, briefly, the evidence of compression is

(i) The effects of general increased intra-cranial pressure as evidenced by pulse, etc.

(ii) Effects of local cortical pressure as shown by convulsions or paralysis.

(iii) The rate at which the cerebro-spinal fluid comes out on lumbar puncture.

Possible later effects of cerebral compression.

1. A delayed compression oedema, generally associated with cerebral laceration.

2. Meningo-encephalitis—usually due to infection.

IV. Dangers of fracture of the base of skull

The gravity of fractures of the base in contrast to those of the vault is mainly due to the relation of the dura to the bone; in the former the dura is invariably torn; whereas in the case of the vault the dura separates with the greatest ease and may escape being torn.

Anterior fossa. There is no immediate danger, but the injury is liable to delayed sepsis owing to its communication with the nasal cavity.

Middle fossa. The dangers are both immediate and remote, because an extensive hæmorrhage very often accompanies the fracture and because the line of it may involve the sella turcica and endanger the pituitary or its stalk; remote, because the communication with the ear may induce sepsis.

Posterior fossa. Fracture of this fossa causes the most immediate concern because of its proximity of the vital area of the medulla, but on the other hand they are in a large measure free from the risks of secondary infection.

Treatment

I. General

Undress the patient with the minimum disturbance.

Put him to bed with the head on one side without a pillow.

Ice bag or cold compress should be applied.

Concussion is tantamount to shock and the treatment should be carried out accordingly. Hot-water bottles, fluids preferably by mouth, otherwise subcutaneously or rectally. Intravenous methods are inadvisable because a sudden rise of blood pressure may initiate bleeding or may produce cerebral œdema.

Restlessness. Put the patient in a dark quiet room. Restlessness may indicate the onset of compression. Morphine should not be given. Bromides and chloral gr. 15 to 20 each should be given. If the patient is unable to swallow, paraldehyde, one dram per stone of body-weight, made up with mucilage of acacia in a proportion of two parts to one of mucilage, may be given per rectum. If this is not effective, hyoscine should be given.

II. Local

Fractures involving the vault.—It is better to shave the head or cut the hair as short as possible. This will enable better examination and the ice cap or cold compress will be more effective. Moreover the part will be kept ready for immediate operation if necessary.

Simple fissured fracture. This should be left alone.

Compound fissured fracture. The wound should be cleaned, and necessary treatment for the general condition adopted. Watch should be kept for symptoms of compression.

Depressed fracture. If it is pressing on the brain, it must be operated on and the pressure relieved. Otherwise it should be left alone.

Fractures involving the base.—The same line of treatment as already indicated should be undertaken. All obvious sources of infection must be avoided. Put a few drops of 5 per cent argyrol into the auditory meatus and if possible spray the nose with the same solution.

Restlessness is usual and should be treated at an early stage with judicious sedatives.

The pulse, respiration, temperature and blood pressure should be recorded every two hours and the bladder should be watched.

Treatment of compression.—Compression due to extra-dural hæmorrhage may appear at any stage but if it be due to cerebral œdema it generally manifests itself after 24 hours by deepening unconsciousness and alteration of the character and frequency of the pulse, blood pressure, respiration and temperature as described above.

When symptoms of compression appear the following treatment is advised:—

Lumbar puncture. If there is moderate rise of pressure, the fluid should be drained until normal pressure is attained.

If there is excessive rise of pressure, hypertonic therapy is indicated. If the patient is able to swallow, 2 drachms of magnesium sulphate in 2 ounces of water are given and thereafter 1 drachm of the salt in 2 ounces of water is repeated every two hours until a watery motion is evacuated. If swallowing is impossible, 3 ounces of magnesium sulphate in 6 ounces of water are given as an enema. The injections may be repeated if necessary. Hypertonic solution such as 50 per cent glucose or 30 per cent saline, injected intravenously, is powerful in lowering the intra-cranial pressure. Moreover, a hypertonic solution of glucose and saline will combat the shock very well. If the symptoms reappear, treatment should be repeated. This is all that should be done in a small dispensary. In *tehsil* headquarters dispensaries further treatment as detailed below may be carried out.

If compression persists or increases in spite of the above treatment, it is not simple general cerebral œdema. It is more likely to be hæmorrhage which is slowly but insidiously progressing and one is forced to decide whether to operate or not. If operation is decided, it must be done as soon as possible and it cannot be expected that a local decompression will afford relief to a brain that is already water-logged.

Technique of operation

Local anæsthetic, 1 per cent novocaine with adrenaline, is used. The infiltration is carried out along a line which extends vertically upwards from the zygoma, one inch in front of the external auditory meatus for a distance of 3 to 4 inches.

The superficial tissues are divided, temporal fascia is incised, fibres of the temporal muscle

are split and retracted and the bone of the temporal fossa is exposed. The bone is perforated with a trephine or bur at a point about two finger-breadths above the zygoma and with a pair of nibbling forceps the vault is cut away until an aperture $2\frac{1}{2}$ inches in diameter is made. If there is a clot, it should be removed and most likely the middle meningeal artery will be found ruptured and if so it should be ligatured.

Failing this, the dura should be opened in a cruciform manner, avoiding the dural vessels. If they have to be divided, they should be picked up with a fine round needle and stitched and each ligatured individually.

The dural flaps are widely separated, the split in the temporal muscle is restored by a few interrupted catgut sutures, temporal fascia is

united with a continuous catgut suture and the edges are united with silkworm gut or horse hair.

If there are still signs of further compression, alimentary dehydration as already indicated should be continued. Failing that similar decompression operation may be done on the opposite side.

After-treatment

The patient should be kept in bed for 3 to 4 weeks, on a low diet with abundant fluids. Half an ounce of magnesium sulphate solution should be given every morning. Ten grains of potassium bromide should be given every day. If the patient is suffering from insomnia, 2 gr. of luminal or $7\frac{1}{2}$ gr. of medinal, or 5 gr. of soneryl may be given.

A Mirror of Hospital Practice

AN INTERESTING CASE OF SUB-TERTIAN MALARIA

By A. K. GHOSE, L.M.F., L.T.M.

Medical Officer, Ambari Tea Estate (Dooars),
Jalpaiguri

It was reported to me that a boy, aged about 10 years, of weak constitution, with slight irregular fever for the past two or three days, fell down unconscious. I lost no time in going to see the boy and found him in the following condition :—

16th June, 1937. Completely unconscious with violent spasms and struggling.

Spasm of the jaw muscles.

Rigidity of back and neck muscles. Pupils dilated.

Spleen slightly palpable under the costal arch.

Temperature— 100.4°F .

Sub-tertian malaria was suspected. Blood films were taken and quinine bihydrochloride (gr. 5) was injected intramuscularly without delay.

Blood examination—Malignant tertian rings ++++. Growing schizonts +.

Evening temperature— 99.2°F . Condition unchanged.

Quinine injection repeated.

Blood examination—Rings and some growing schizonts.

17th June. Morning temperature— 98.6°F . Pulse and respiration normal.

No spasms or strugglings. He could now take fluid diet.

Quinine injection (gr. 5) repeated.

Evening temperature— 99.4°F . Condition much better.

One tablet of quinine bihydrochloride (gr. 5) was swallowed.

Blood films—Degenerated rings + +.

18th June. Morning temperature— 99°F .

Evening temperature— 99.6°F .

Alkaline mixture two tablets of quinine bihydrochloride (gr. 10) were ordered daily. No other complications appeared and he took solid food (rice) and talked distinctly.

Blood examination—Rings (degenerated) a few only.

19th June. Temperature normal.

Blood showed no parasites. He made an uninterrupted recovery.

Discussion

It is recognized by all the leading authorities (Stitt, Manson, Knowles) that the schizogony cycle of sub-tertian parasites is almost always confined to the internal organs and only rarely in heavy infections—usually in fatal cases (Knowles)—does this stage appear in the peripheral blood.

The point of interest of the case under report is that, though there was heavy infection, it was very easily controlled by administration of quinine in moderate doses given intramuscularly. The intravenous route was not adopted in consideration of the age and weak state of the patient.

Conclusion

I sent the blood smears to the protozoological department of the Calcutta School of Tropical Medicine to corroborate my findings. Dr. Das Gupta very kindly examined the blood slides and confirmed my results, and I take this opportunity of expressing my gratitude to him. He remarked 'It is incorrect to believe that the cases showing the schizonts of *P. falciparum* in the peripheral blood always prove fatal. Of course, these are bad cases'.

I examined his blood daily for 11 days for crescents but without any success. After this period he refused to be subjected to more pin-pricking, so I could not follow up the case further.

APPENDICITIS IN A CASE OF TRANSPOSITION OF VISCERA

By R. D. MACRAE

CAPTAIN, I.M.S.

Civil Hospital, Mercara, Coorg

A young male was admitted into hospital with pain in the right side of the chest, cough, occasional fever and shivering. On examination the patient was found

to be well nourished. The apex beat of the heart was in the fifth intercostal space on the right side, two and a half inches from the mid-sternal line. The temperature was normal. The spleen and liver were not palpable; no malarial parasites were found in blood films. There was diminished vocal resonance with impaired breath sounds over the lower lobe of the right lung. In the left iliac fossa hyperaesthesia was elicited over Sherren's skin triangle, with deep tenderness over an area corresponding normally to the lower six inches of the descending colon. This was assumed to be due to an inflamed and distended vermiform appendix, transposed to the left side. Rovsing's sign, elicited by pressure over the right iliac fossa, was found to be positive.

The condition of the chest responded well to rest, counter-irritants, and stimulating expectorant mixtures. After a few daily enemata the abdominal signs disappeared, except for the tenderness. No ova or protozoa were found in the stool; and the urine was normal. Post-mortem investigation was not possible. Autopsy revealed nothing abnormal.

The abdomen was opened by the left paramedian incision under evipan sodium and inhalation anaesthesia; the appendix was found inflamed and adherent to the caecum near its tip and it contained a small faecal concretion. It was removed, and the abdomen explored. All organs were transposed. The spleen, lying in the right hypochondrium, was slightly enlarged. The abdominal aorta divided at the level of the third lumbar vertebra and the iliac arteries ran downwards, almost parallel to each other as far as the pelvic brim. The abdomen was closed, without drainage, and the patient made an uneventful recovery.

TREATMENT OF GANGLION*

By A. K. DUTT GUPTA, M.B., D.T.M.

Resident Surgeon, Medical College Hospitals, Calcutta

A GANGLION is a cystic swelling usually found in the region of the wrist or the ankle. The origin of a ganglion may be either sudden, after a trauma, or insidious and slow. The aetiology is not definitely known.

The usual symptoms are slight weakness and some pain; the unsightly condition also worries the patient. The swelling does not move on the movement of the tendons but it may be made more apparent when they are stretched. The treatment may be either non-operative or radical surgical operation.

Many authorities recommend a preliminary trial with conservative measures at first.

- (a) The cyst is ruptured by gradual pressure or by a sudden blow. It is painful and there is recurrence later.
- (b) The contents are aspirated and some irritant injected such as iodine, carbolic, and quinine urethane. Mercer, quoting Gunther, describes the injection of collodion into the ganglion and Hamilton Bailey also advocates this form of treatment.

The surgical treatment consists of a complete removal of the whole of the cyst wall, otherwise

recurrence takes place. A general anaesthetic is necessary; often the cyst has a broad base and very often communicates with a joint cavity which is opened by the operative procedure. Even then it is very difficult to remove the whole wall without causing injury to the tendons or capsule of the joint. Strict asepsis is essential.

In view of the facts that operative treatment is not always possible in the out-patient department and also that preliminary conservative treatment is advocated by many authorities, the following plan of treatment was adopted on a series of unselected cases with encouraging results. The limb was put in a plaster-of-Paris casing and kept fixed in the position of rest for four to six weeks and a short course of ultra-violet rays was applied. In every case, the swelling had entirely disappeared, when the plaster was opened. It is of course very difficult to make the otherwise healthy patients keep the plaster on for the desired length of time without soiling or softening it with water.

The two following case reports are typical of the series :—

Case 1.—A young athlete had a ganglion on the dorsum of the hand, the size of a very large marble, for more than four months. It had incapacitated him from active work. X-ray examination showed no bone or joint defect. After four weeks' immobilization in plaster in gentle dorsi-flexion, the swelling had entirely

Fig. 1.—Bilateral ganglion before treatment.

disappeared. A short course of ultra-violet rays was administered. He was seen ten months afterwards and there was no sign of recurrence of the ganglion. He can now do any work, including weight lifting.

Case 2.—A girl, 12 years of age, had a ganglion on the dorsum of each foot. X-ray examination did not reveal any bone or joint disease. The left foot, which had the bigger ganglion, was treated and the right foot

* Abridged by the Editor.

left untreated as control. Figure 1 shows the condition before treatment and figure 2 shows the feet after treatment. It will be noted that the ganglion on the left foot has completely disappeared.

Cases that could be followed up have shown no recurrence in a year.

This method may be tried with advantage on all cases before a surgical operation is undertaken. It will be specially useful in patients who are unwilling or are unsuitable for operation.

Fig 2.—After removal of plaster. Left foot shows disappearance of ganglion, compared to right side—untreated (same case).

It has advantages over the injection method that the latter is painful, may give rise to inflammation with subsequent fibrosis, and if unsuccessful the subsequent operation is made more difficult.

I wish to thank the house surgeons of the surgical out-patients department who took much interest in the work.

A REMARKABLE NATURAL CURE OF STRANGULATED HERNIA*

By A. K. DUTT GUPTA, M.B., D.T.M.

Resident Surgeon, Medical College Hospitals, Calcutta

NATURAL relief of a strangulated hernia by the formation of a faecal fistula is not altogether unknown especially in neglected femoral hernia. Prolapse of the gut through the fistula is very rarely seen and the case to be described is still more unusual as there was a double prolapse, one

of the ileum and the other of the ascending colon through a fistula in the caecum.

The patient, over 50 years of age, had severe pain and swelling in the right inguinal region, about three weeks before coming to the hospital. The pain and vomiting lasted for two days after which the swelling burst with discharge of faecal matter and he was relieved. After about a week he found two portions of gut protruding through an opening in the skin.

When he came to hospital, he was very weak and emaciated from constant discharge of fluid faeces from the small intestine. On examination, a red smooth protrusion about five inches long with a slight concavity towards the left and a small central hole at the end was found dangling near the pubis. Another globular swelling, greater in diameter but shorter in length, was found on the right side of the first protrusion. Both of these were oedematous with small multiple ulcers and sloughs. It presented the appearance of a decorticated penis and scrotum. The central opening looked like the external urethral orifice and as the opening of the other swelling was pointing posteriorly it was not seen.

After a few days of preparation the man was operated upon. The prolapsed portions of gut were pushed into the abdomen through the opening. Even then it was not certain that the rent was in the caecum. It was suspected that a loop of gut had become gangrenous and fallen off and the two prolapsed portions were the ends of the gut left by separation of the gangrenous loop. The mucous membrane being ulcerated, did not give the appearances typical of large and small intestines. After enlarging the opening and careful dissection the damaged portion of the gut was pulled out and was found to be the caecum. The appendix was present posterior to the rent. The interior of the caecum was extensively ulcerated. The lower end of the ileum and proximal part of the ascending colon were mobilized sufficiently, the caecum was excised and an end to end anastomosis was done between the ileum and the ascending colon without opening up the general peritoneal cavity, which was shut off by adhesions. The patient made a remarkable and uneventful recovery and left hospital a month after the operation.

Indian Medical Gazette

JANUARY

THE RESEARCH WORKERS' CONFERENCE AND MEDICAL RESEARCH IN INDIA

THE Indian Research Fund Association was founded in 1911, and its comparatively small capital and annual income of five lakhs was administered by a governing body and an expert advisory committee. It was not possible to bring into being a large body of expert investigators at a moment's notice, and although an immediate expansion of research activities in India followed the founding of the association, the governing body decided to conserve the funds of the association as much as possible during the period of training of an adequate personnel, rather than squander them on amateur schemes of research, and eventually to build a central research institution which would be the kinetic nucleus, so to speak, of medical research in India. The development of this scheme was held up by the war, but the funds of the association continued to accumulate. Meanwhile, however, the conditions which had produced stasis at the centre had stimulated activity at the periphery and, both in Bombay and Calcutta, there were schemes for furthering medical research and for founding schools of tropical medicine in each of India's rival commercial centres. Largely as a result of the strong material support from the commercial community, in particular the tea, jute and mining associations, and of the dynamic personality of Sir Leonard Rogers, the government of Bengal decided to go on with their project, whereas the government of Bombay dropped theirs.

The gods help those who help themselves, and the Calcutta school received a considerable grant from the Indian Research Fund Association for a number of years—and they are still receiving a proportion of this grant—but the idea of a large central research institute was still visualized and slowly became more concrete. Then in 1923 the Inchcape axe fell and the whole of the annual government contribution of Rs. 5 lakhs was discontinued.

There had always been two schools of thought regarding the central research institute, one favoured the concentration of both funds and personnel in this central institute and the other the strengthening of the already active provincial institutions, the School of Tropical Medicine in Calcutta, the Haffkine Institute (later named) in Bombay, the King Institute in Madras, etc. This financial crisis had the effect

of widening the gap between the two schools of thought; the centripetal school considered that a halt should be called in medical research in India until times improved so that the capital fund might be conserved, whereas the centrifugal school considered that a steady development of a research personnel was far more important than bricks and mortar and that, even if it meant eating into capital to some extent, this would be far better than stopping the research schemes already in progress and dispersing trained personnel.

It was at this point that Sir John Megaw—at that time Director of the Calcutta School of Tropical Medicine—made the suggestion that the opinion of medical research workers in India as a whole, and not simply of the one or two senior members attached to the central research laboratory at Kasauli, should be ascertained. This suggestion was taken up readily by the Director-General, who invited all provinces to send delegates, and the first All-India Conference of Medical Research Workers was held in the autumn of 1923 at the School of Tropical Medicine in Calcutta.

The conference had no executive power—and never has had to this day—but here the whole position was discussed and the weight of opinion was so much in favour of continuing the research programme, even at the sacrifice of capital, that this policy was recommended by the scientific advisory board and adopted by the governing body of the fund. Fortunately, the financial atmosphere improved very quickly and soon the grant was restored, in part at first and finally altogether.

This first conference, designed as a 'business' meeting to discuss ways and means, took on a valuable scientific application as well, gave research workers from different parts of India an opportunity to express and exchange their ideas on the various research problems, mitigated the dangers of isolation, for example the staleness that engenders despair or, conversely, self-complacency, and altogether was such a success that it was decided to make it an annual event; in the intervening fourteen years there have been fourteen conferences.

During these fourteen years the conference has undergone certain changes: one development has been that of natural growth, both in the number of delegates which were originally about thirty and have now risen to over a hundred, and in the amount of business transacted, which despite the fact that much of this is done by the sub-committees that have been formed for all the most important subjects, e.g., malaria, nutrition, cholera, tuberculosis, plague, leprosy, maternal mortality and rabies, it would never have been possible to finish in the week allotted for the conference but for the efficiency of a chairman who keeps speakers rigidly to the point and the continence of many of the delegates who

maintain a silence despite the fact that they feel they may have something relevant to add to the discussion.

Another, more subtle change that the conference has undergone is perhaps best reflected in the change in its composition; the delegates at the first conference were with few exceptions the research workers themselves, but there has been from the early days an increasing tendency for senior administrative officers and directors of public health to attend, so that at the 15th conference these easily outnumbered the research workers themselves. This change is, we believe, again a reflection of a change in the general attitude towards medical research and indicates an increasing enthusiasm, not simply to carry out research—this always existed—but to put into practice the results of this research, both by those responsible for medical relief and those concerned with prevention of the spread of disease. This intrusion into their conference is certainly not resented by the research workers, as, if the director of public health gets valuable suggestions from the research worker, the latter gets indications as to the direction in which the work is most likely to be productive and he learns of medical problems of which he possibly did not know the existence. That is to say the tendency is not to treat the medical research worker as a peculiar person who works and thinks on a different plane and whose language differs from that of the ordinary medical man, but to meet and understand him and the work he is doing, and if possible apply it. The spirit of mutual understanding and co-operation must lead to the general advancement of medical science in India and would certainly not have been achieved so early had the research workers' conference never come into existence. It is, however, a question whether with the change in its character it should not also change its name and become the All-India Medical Research Conference.

It is not our intention to give a history of the conference and follow it through its fifteen meetings, nor to discuss the part it has played in the shelving of the expensive central research institute scheme, nor to trace in detail its influence on the development of medical research in India, but simply to remind our readers of the origin and functions of this conference, it has, as we have already said, no executive power but its opinions have always carried weight and the governing body has never taken any action which could be said to be directly opposed to the views expressed by the majority amongst the members; and on two occasions at least complete reversals of policy have been brought about by strong resolutions sent forward by this conference.

This year for the first time the conference met at the Imperial capital and His Excellency the Viceroy, Lord Linlithgow, did the conference the honour of himself opening the first session. His

Excellency has always taken a very keen interest in medical research and was for some years before he came to India chairman of the Medical Research Council of His Majesty's Privy Council: his opening address is printed elsewhere in this number. His interest will do much to establish even more firmly the importance of this annual conference and to stimulate a wider interest in medical research in India.

MEDICAL STATISTICS

WE maintain that the intelligence of the physician and particularly of the physician engaged in clinical research is above the average of that of the community from which he comes; quite often, nevertheless, when he is presented with the simplest statistical problem, his brain appears to become completely paralysed and he is so self-conscious of the limitations of his knowledge that not only does he fail to understand his subject, but he won't even try to do so, and seems to be as unable to apply his native intelligence as would an aboriginal tribesman in similar circumstances.

This is partly the fault of the physician, or to be more precise of the education systems under which he has been taught in his pre-medical and medical student days and which have not taught him to apply his common sense, and partly the fault of the statistician, who has invented a language and even a script of his own, so that the average physician at a statistical conference would find himself as completely lost as would a Japanese peasant if he were suddenly planted in Piccadilly Circus.

The language of the statistician is not, any more than that of the physician, invented, as many people seem to suppose, in order to confuse the outsider—or, as the cynic would say of all language, in order to conceal thoughts—but to facilitate, and above all to abbreviate, communication between experts. Nevertheless, it does confuse the outsider, and consequently most books on statistical methods are quite incomprehensible to him.

This is a very great pity because the need of a sound knowledge of statistical methods is apparent in practically every number of every medical journal that one picks up. Consultation with a statistician is often very helpful, but if the research worker postpones this until after he has produced his results he may meet with disappointment, as often he will be told that the conception of his investigation and his methods of collecting data are fundamentally wrong and that no amount of statistical analysis will turn his pig's ear into a silk purse. Even if he consults the statistician at the beginning of his enquiry he may later have to change his methods to meet circumstances. It is therefore almost essential that he himself should have a substantial grounding of knowledge of statistical

methods. A number of excellent books have been written with the object of teaching the elements of statistical methods to the practical investigator and of facilitating the liaison between him and the statistician, but none, in our opinion, has been quite elementary enough. For this reason, we consider that from the point of view of medical research work, the most valuable series of articles to appear in a medical journal recently have been those by Dr. Bradford Hill on medical statistics, which were published each week in the *Lancet* during the first few months of last year. We were therefore particularly pleased to receive for review

the volume in which these articles have been reprinted*.

This writer does seem to have achieved what others have failed to achieve and brought himself down to the level of comprehension of the statistically-innocent practical research worker, without exactly insulting his intelligence. We commend this little book to all medical research workers and particularly to would-be contributors to this journal.

THE CHEMOTHERAPY OF STREPTOCOCCAL INFECTIONS

By U. P. BASU, D.Sc., F.R.S.

and

S. P. DE, M.B.

(From the Research Laboratory, Bengal Immunity, Baramore, Calcutta)

CHEMOTHERAPY is usually regarded as a treatment of disease by chemical substances which by biological test have previously been proved to be relatively much more toxic to pathogenic organisms than to human or any other animal being. From clinical observations it is now known that protozoal diseases, such as malaria and syphilis, readily yield to certain specific chemical remedies while no bacterial infection in human beings can be checked *in vitro* by any such substance. Recent researches have, however, brought to light the possibility of combating streptococcal infections by means of chemical compounds having a selective action and accordingly the former belief that bacteria are more resistant than the protozoa can no longer be upheld.

History

It may be pointed out that chemotherapeutic research requires a close co-operation between clinicians, biologists and chemists. In the case under discussion it was already known that the different cocci are responsible for various diseases like tonsillitis, erysipelas, gonorrhoea, pneumonia, scarlet fever, puerperal sepsis, etc. The organisms again can be easily collected, cultured, grouped and classified. It is only the isolation of a number of chemically-related substances having bacteriostatic and bactericidal action in blood and tissues that has now led the chemists to tread on this new pasture. Of course, on the chemical side researches practically started from the discovery of Domagk (1935) that a red dye, the hydrochloride of 4-sulphamido-2:4-diamino azo-benzol (VII),

had a specific action against hæmolytic streptococci. It was clinically tested by Klee and Römer (1935), Schreus (1935) and Levaditi and Vaisman (1935). As usual, once certain knowledge of the chemical constitution of a drug is obtained, other substances more-or-less closely related to it would be synthesized and tested for their chemotherapeutic properties. In this way the chemist might have to adopt a blind method and roam in darkness before he was fortunate enough to come upon a '606', '710' or '914'. In the present case it was very soon pointed out by Tréfouël *et al.* (1935) that the azo compounds which did not contain a sulphonamide group attached to one benzene nucleus were inactive, whereas the substituents in the other nucleus might be varied without influencing the protective power. They further noted that the diazo-linkage itself was not essential and that the parent compound p-aminobenzene-sulphonamide (VI) was equally therapeutically active—an observation since confirmed by Colebrook and Kenny (1936). Colebrook *et al.* (1936) have further observed that p-aminobenzene-sulphonamide has a bacteriostatic and bactericidal action against a small number of hæmolytic streptococci in culture media and in blood, whereas the red dye, better known as prontosil-red, is inactive. On reduction, however, it affords an active substance indicating thereby that the prontosil may become altered in the system to give rise to the active substance sulphonamide. That reduction may be the factor in the activation of prontosil seems also reasonable from the fact that hæmolytic streptococci can, under certain conditions, bring about the reduction of some chemical substances. The proof (Fuller, 1937) that a considerable amount of sulphonamide is excreted when prontosil is given by mouth or injection, clearly demonstrates that the animal system is able to break down the dye to p-aminobenzene-sulphonamide which is then the actual active substance. These observations have resulted in the production by several firms

of p-aminobenzene-sulphonamide under different names such as :

Prontosil album.....	from Bayer
Sulphonamide P.....	„ British Drug Houses
„	„ Burroughs Wellcome
Colsulanyde.....	„ Crookes Laboratories
Streptocide.....	„ Evans, Lescher and Webb
Bi-Sulphonamide....	„ Bengal Immunity

All these compounds are believed to be very similar in composition but for its clinical use the compound must be chemically pure, melting correctly at 166 to 166.6°C. Here it may be said that the organic chemists are generally accused of working in the direction to increase the pages and volumes of *Beilstein Handbuch der organische chemie*. But this new chemotherapeutic compound was first synthesized in the year 1884 by a method which involves the action of sulphuric acid on aniline (I) at an elevated temperature, converting the resulting sulphanilic acid (II) to its sodium salt and reacting this with acetic anhydride to afford the p-acetyl amino derivative (III). This latter compound with phosphorus pentachloride gives rise to the product (IV) which on treatment with ammonia yields the acetyl derivative (V) and this on subsequent hydrolysis affords p-aminobenzene-sulphonamide (VI). The reactions are represented by the formulæ below :—

Thus, a product obtained by the most common organic reactions is now being found to possess bactericidal property at a time when repeated failures with various antiseptics had led all to conclude that the disinfection of the blood stream in septicæmia would ever remain an impossibility.

Chemical constitution and therapeutic activity

The question now, naturally, arises whether this antistreptococcal action is the exclusive property of p-aminobenzene-sulphonamide. Fourneau *et al.* (1936) have shown that the alteration of the amino group to *ortho* or *meta* position, or replacement of the sulphonamide group by other groups results in loss of activity. Tréfouël *et al.* (1937) further pointed out that an additional substituent particularly in the *meta* position with respect to the sulphonamide group was unfavourable. The combination with/or replacement of the amino group again lowers the activity of the compound. Recently Gray *et al.* (1937) have, however, synthesized a few compounds—p-methoxy-benzylidene-p-aminobenzene-sulphonamide, p-dimethyl-aminobenzylidene-p-aminobenzene-sulphonamide—which are

being claimed to be as active as prontosil in streptococcal infections in mice and are from 2 to 16 times less toxic. But as all these compounds might readily give rise to free p-aminobenzene-sulphonamide, the efficacy of the compounds themselves might be questioned. Another product, p-benzyl-aminobenzene-sulphonamide, which does not contain a free 'p-amino' group, nor one which should readily yield free p-aminobenzene-sulphonamide, is being considered to be less toxic but less effective than the latter compound (Gray *et al.*, 1937). That the activity of p-acetyl-aminobenzene-sulphonamide (V) is one-third of that of sulphonamide (Buttle *et al.*, 1936) clearly points to the necessity of the presence of a free 'p-amino' group. The higher dosages often required in sulphonamide treatment might then be accounted for by its partial conversion (Marshall *et al.*, 1937) to less active p-acetyl-aminobenzene-sulphonamide.

Regarding the 'sulphonamide' part, it may be said that an increase in its number in the benzene nucleus does not in any way increase the streptococcal activity (Buttle *et al.*, 1936). Replacement of the amido hydrogen by a phenyl radical (IX, R = Ph), however, does not alter the special characteristic of the product. On the contrary, its replacement by 8-quinolyl, 6-methoxy 8-quinolyl, or α -diethyl-butyl which are known to afford important therapeutic compounds increases the toxicity of the compound. That the bactericidal property is not exclusively due to the presence of the sulphonamide grouping, —SO₂·NH₂—, is again evident from the recent observations of Buttle and his co-workers (Buttle *et al.*, 1937). They have found that 4, 4-diamino-diphenyl sulphone (X) is active in curing streptococcal infection in mice in doses of about one-hundredth of those required with p-aminobenzene-sulphonamide. It is, however, 25 times as toxic as the latter compound. Similarly dinitro 4, 4-diphenyl sulphide, dinitro 4, 4-diphenyl disulphide, and 4, 4-diphenyl sulphone—none containing any sulphonamide grouping—have been found to be more active than sulphonamide in experimental hæmolytic streptococcal infections (Fourneau *et al.*, 1937). These as well as the observation of Gley (1937) that p-acetyl-amino-thiophenol (VIII) possesses an antistreptococcal action, clearly indicate that this specificity might be exerted by bodies containing sulphur in one or other form. Of course, at present there is no knowing when these investigations of the biologists and chemists would reveal an ideal drug for the treatment of bacterial infections.

Attention has also been directed towards the isolation of a soluble form of this important drug (its solubility being only about 2 per cent at the body temperature). But under normal conditions the introduction by injection has no advantage over oral administration as a subcutaneous injection of the drug does not lead to a higher blood concentration than when it is

given by mouth. Even after intravenous injection a small fraction remains in the blood stream; obviously the sulphonamide passes readily from the blood into the tissue (Marshall *et al.*, 1937). Further an injection of a solution of the drug left over for a period of time may give rise to other toxic symptoms [cf. De and Basu (1937)]. The sulphonamide is rapidly (within about four hours) absorbed from the gastro-intestinal tract, enters practically all the body fluids including the saliva, pancreatic juice, bile and cerebrospinal fluid, and is excreted rapidly and almost entirely by the urinary tract, partly in unchanged form and partly as an acetyl derivative. The difficulty is that it is necessary to give large doses by the mouth. This is sometimes inconvenient or difficult and often may give rise to other troubles.

Toxicity and dosage

In *in vitro* experiments a small inoculum of streptococci in blood is destroyed by the amide even when present in so low a concentration as 1 in 18,000. Tests on mice have proved that the average lethal dose for animals of 20 gm. weight is about 150 mgm. (Whitby, 1937). This is several times the full effective dosage; our investigations (De and Basu, 1937) tend to show that 7.5 mgm. will protect mice against virulent streptococci. The patients have been found to tolerate 4 to 6 gm. (60 to 90 grains) of sulphonamide daily for as long as a month without any undesirable ill effect. The acute toxic dose of the drug for human beings is of the order $\frac{1}{2}$ to 1 lb., a dose very far away from the daily dosage of 3 to 4.5 gm. The dose in moderate cases is two 0.5 gm. ($7\frac{1}{2}$ grains) tablets three times daily. Maintaining a clinical improvement for 2 days one tablet of 0.5 gm. three times daily for 3 to 4 days would complete the treatment. In severe cases it is advisable to take three 0.5 gm. tablets three times a day and after an improvement the dose may be reduced to two tablets daily and maintained at this dose for a few days. In critical cases the treatment should be commenced with high doses, intramuscular [either with prontosil (2.5 per cent) or sulphonamide in normal saline] and oral therapy being combined. The dose of intramuscular injection may vary from 10 to 25 c.cm. daily. The dose for children should be calculated accordingly. It is advisable, however, that 3 to 6 drops of dilute hydrochloric acid should be given with each dose of the drug to children up to two years. The tablets should always be taken after meals with a large amount of water to avoid gastric disturbance and as the compound is not unpalatable to taste the tablets should be chewed before being swallowed so that the absorption may begin from the mouth. In the case of any gastric disturbance either the dose may be reduced or a small amount of dilute hydrochloric acid

may be taken. Barring a sort of lassitude and dizziness during treatment the drug is found to be non-toxic under usual conditions. A serious nephritis is the only important contra-indication (cf. Anghelescu *et al.*, 1937).

In general the drug is well tolerated but the time of administration is important as the maximum therapeutic effect is not seen until after 48 hours (Long and Bliss, 1937b). This might be due to the fact, as recently pointed out by Finklestone-Sayless *et al.* (1937), that sulphonamide might have a much more efficient bactericidal action upon cultures that have passed through the logarithmic phase of growth than upon young cultures. It is less toxic than prontosil-red, so that it is possible to obtain a better protection by giving larger doses. But it must be pointed out that though sulphonamide is more useful, its toxicity and other by-effects are not at all negligible. Usually it is excreted entirely by the urinary tract within a short period (3 to 4 days); but in case there is any renal impairment, this excretion may be hindered causing further injury to the kidneys. In its clinical application certain toxic symptoms such as cyanosis owing to the formation of sulphæmoglobinæmia has been often observed (Discombe, 1937). For this reason it is often dangerous to prescribe the drug to Indian women as anæmia is present in a considerable percentage of them. Recently Areher and Discombe (1937) have thoroughly studied the cause of the formation of sulphæmoglobinæmia and have opined that free and unabsorbed sulphuretted hydrogen in the system, often formed therein by the action of bacteria on food residues, or as a result of administration of sulphur or sulphur-containing compounds, would promote the development of sulphæmoglobinæmia. This is further enhanced by the presence of substances which might act as a catalyst in the process of combination of hæmoglobin with sulphuretted hydrogen. For this, the prescription of magnesium or sodium sulphate to sulphonamide-treated patients should be avoided (Paton and Eaton, 1937). For its prevention 'the colon must be kept free from food residues by (i) cleansing it with enemata before treatment is started, if purges have previously been given; (ii) giving the patient a low residue diet, of adequate caloric value containing few eggs; and (iii) lastly giving large, regular doses of liquid paraffin'. Over and above the blood of the patients receiving the drug should be spectroscopically examined, as mere development of cyanosis does not necessarily indicate that it is due to the administration of the drug—this being often caused by other concomitant diseases, such as pneumonia. In the absence of sulphates, or any sulphur or sulphur-containing preparations like compound liquorice powder, sulphur-containing diet, and even local dressings containing sulphur, large doses of sulphonamide may be well tolerated. But a high dose (12 to 24 gm. per diem) again may result in the

formation of methæmoglobinæmia, when inhalation of oxygen would help in its disappearance within a day (Paton and Eaton, 1937). Another by-effect in the form of a characteristic febrile reaction causing the body temperature to rise was noticed by Hageman and Blake (1937). Acute hæmolytic anæmia (Kohn, 1937), toxic optic neuritis (Bucy, 1937) and different forms of dermatitis and dermal eruptions (Goodman and Levy, 1937) have often been reported but these do not produce any permanent injury and the symptoms are generally found to clear up on withdrawal of the drug.

The drug is an excellent prophylactic measure to minimize the risk of puerperal septicæmia and is of special value in abortion. It has been successfully used in the prevention of otitis media, arthritis and other infections which have been more fully discussed later on. In the treatment of all cases, however, the presence of hæmolytic streptococci must be verified by bacteriological examination. In a recent letter to the editor of the *Lancet*, Colebrook (1937) has rightly pointed out that 'it is hardly justifiable to use it as a prophylactic measure in quite normal childbirth. For deliveries involving "interference", i.e., operative delivery, internal version, manual removal of placenta, etc., when the risk of sepsis is known to be greater in such cases, it must be essential to ascertain whether or no a hæmolytic streptococcus is present in the birth canal after labour, and, if it is not, to discontinue the drug as soon as possible. For this purpose a swab taken 6 to 12 hours after the expulsion of the placenta should be bacteriologically examined'. When a prophylactic measure in obstetrics is to be adopted it is essential to start it (dosage being one 0.5 gm. tablet 3 times daily) some hours before the probable time of delivery and repeat the dose at 6-hourly intervals for 3 or 4 days. If there be any complaint by the patient of lassitude and dizziness, the dosage should be reduced or the drug discontinued completely. Of course, if it be possible to protect patients in labour from infection with hæmolytic streptococci without any other toxic effect, it would be a marvellous advance in obstetrics.

Mode of action

But in spite of several investigations on various problems little work has yet been done on the way in which this important specific acts on hæmolytic streptococci. Unlike the chemotherapeutic studies with the protozoal infections, it is only the beginning of a similar study in bacterial diseases and it is just a year and a half ago that p-aminobenzene-sulphonamide has been found to be bactericidal against the hæmolytic streptococci *in vitro* and to a limited degree *in vivo*. In clinical experiments, of course, remarkable results have already been obtained. This discrepancy is being explained (Colebrook *et al.*, 1936) by the fact that the

enhanced bactericidal action of the blood is supplemented by that of the tissues of the whole animal. Long and Bliss (1937a) consider the stimulation of phagocytic activity of the polymorphonuclear leucocytes and of the monocytes of importance in the mechanism of action of the drug. On the other hand, examining smears from the peritoneal exudate as well as the histological sections of the liver and spleen of mice after ingestion of the drug Mellon *et al.* (1937) obtained no evidence of phagocytosis. Recently, Finklestone-Sayliss *et al.* (1937) have again observed that the drug stimulates phagocytic activity of the reticulo-endothelial system and also the production of leucocytes by the bone marrow. Another characteristic of the compound is that it possesses a specific action *in vivo* even in cases when it has no such action *in vitro* (Kenny *et al.*, 1937). The streptococcal infection in mice had previously been prevented by infiltration of the inoculated area by acridine antiseptics, such as acriflavine and proflavine. The action of these drugs is directly bactericidal and purely local, whereas the action of sulphonamide is quite a different one and is obtained by introducing it *via* the alimentary tract, or by an injection remote from the site of infection. This has undoubtedly led to a considerable interest in the chemotherapy of bacterial infection and we are now at the beginning of our knowledge about a class of drugs which might combat bacterial diseases as effectively as those which are specifics in protozoal infections.

Clinical reports

Although the drugs in this series have just been discovered, the literature on the treatment of diseases is already an extensive one. This may be roughly divided under the following heads:—

(i) *Puerperal sepsis*: Working with prontosil-red, Anselm (1935) obtained good results in the year 1935 in 13 cases of puerperal fever and also in septicæmia following abortion. Fuge (1935) treated 120 patients suffering from puerperal fever with large doses of prontosil-red and only three died. Ley (1936) reports good results in a number of cases and regards this treatment as superior to other medicaments. Recently, Foulis and Barr (1937) have treated 22 cases of puerperal septicæmia with prontosil album (sulphonamide) with successful result and the drug was tolerated even in large doses. In their study with several cases Colebrook and Kenny (1936) observed the development of sulphæmoglobinæmia in 3 out of 38 patients. A peculiar case of chronic wound infection due to hæmolytic streptococci following puerperal sepsis due to the same organism three years previously is described by Purdie and Fry (1937). The treatment was made with sulphonamide and the patient received for 19 days 1 gm. of the drug 3 times

daily. For one week the wounds were irrigated daily with 1 per cent solution of the drug and after irrigation dusted with the drug in powder form. After discharge further 38 gm. were taken. Thus, a total administration of sulphonamide 95 gm. in all with local treatment with the same drug was followed by sterilization of wounds within three weeks and complete healing in six weeks. It is further reported that other procedures and actinotherapy had failed to give any relief in this particular case.

(ii) *Erysipelas*: Gmelin (1935) treated 10 children with erysipelas and observed rapid improvement. In a comparative study Kramer (1936) noted that injection of 20 c.cm. soluble prontosil reduced the febrile period in 23 cases of erysipelas to 4 days whereas in alternative treatment eleven days were required. Hartl (1936) reports successful treatment of 25 cases of erysipelas in adults. Excellent results in the treatment of this disease, scarlet fever, tonsillitis, impetigo and otitis media are also being reported by Long and Bliss (1937a).

(iii) *Streptococcal and meningococcal meningitis*: Experimenting with rabbits Proom and Buttle (1937) as well as Marshall *et al.* (1937) noticed that sulphonamide on oral administration is present even after 4 hours in the cerebrospinal fluid (0.2 mg. per c.cm.) in somewhat lower concentration than in the blood (0.3 mg. per c.cm.). This concentration (1:5,000) of the drug in the spinal fluid exerts a strong bactericidal effect on the streptococcus in *in vitro* experiments with human blood, and on the meningococcus in culture media. These observations and its comparatively higher solubility in organismal fat (Finklestone-Sayliss *et al.*, 1937) justify its administration in streptococcal and meningococcal meningitis.

Caussé *et al.* (1936) first reported a case of meningitis successfully treated with prontosil. The patient was a man of 46 attacked with hæmolytic streptococcal meningitis of otitic origin. The patient's spinal fluid was sterile in 48 hours. Ten patients with meningococcal meningitis were successfully treated with sulphonamide (Schwentker *et al.*, 1937). Similarly Anderson (1937) in one case and Weinberg *et al.* (1937) in two cases obtained good results by the prompt use of sulphonamide in streptococcal meningitis. Branham and Rosenthal (1937), however, advocate a combined treatment with the drug and serum rather than with either alone.

(iv) *Gonorrhœa*: A close biological relationship between the meningococcus and the gonococcus naturally suggests that the drug might be successfully used against the latter infection. Of course, its use in such cases is still in the experimental stage and the specificity has often been questioned (Anwyl-Davies, 1937). However, certain cases have been successfully treated with this new drug. Dees and Colston (1937) have found that in the majority of cases the urethral discharge and symptoms of burning and frequency promptly disappear. Similarly, Klose

(1936) and Herrold (1937) reported better results with the amide in gonorrhœa. According to Erskine *et al.* (1937) the treatment with the drug along with daily urethral irrigation with potassium permanganate is found to be more promising.

(v) *Bacillus coli infection*: The introduction of this drug is a marked advancement in the treatment of urinary infections. Imhäuser (1935) was the first to note the results of administration of sulphonamide in *B. coli* infections of the urinary system. A number of cases of *B. coli* pyelitis in children was cured by Huber (1936). Kenny *et al.* (1937) have also reported that small oral doses (0.5 gm. tablets 3 times a day for 5 to 7 days) of p-aminobenzene-sulphonamide effect the rapid disappearance of *B. coli* and pus cells from the urine and remission of symptoms in 46 women with urinary tract infections. Helmholtz (1937b), who previously (1937a) reported striking results with this drug in treating infections with *B. coli*, opines that sulphonamide is even better than the other urinary disinfectant, mandelic acid, especially in infections with *B. proteus* and *Acrobacter aerogenes*.

(vi) *Streptococcal septicæmia and other infections*: Robinson (1937) treated a case of streptococcal septicæmia with prontosil. Roth (1935) reported good results in rheumatic endocarditis and Recknagel (1935) in tonsillitis, pneumonia and rheumatoid arthritis. prontosil-red was also successfully used in 3 cases of typhus (Schmidt, 1936). In affections of the skin and mucous membrane, Jaeger (1936) advocates its local application. He also used it locally in a solution or as dressing in wounds, boils, carbuncles, eczema and various fungus infections of the skin. In cases of Ludwig's angina and cellulitis of the legs with septicæmia death has, however, been recorded (Long and Bliss, 1937a). Quite recently (Van der Wielen, 1937), prontosil has been used in a case of quartan malaria with apparent success.

Conclusion

Previous to the discovery of this drug puerperal fever and other streptococcal diseases were generally treated with biological products which are usually inconvenient and have other drawbacks. It is now evident that the sulphonamide for its rapidity of action and simplicity of administration is being found to be specially valuable in various streptococcal and other bacterial infections. Its cheapness in comparison with other medicaments is also an additional advantage. Of course, as already pointed out, the consequences of its use are increasing in complexity. Moreover, it has been recently shown (Bliss and Long, 1937) that the compound has no bacteriostatic action against organisms of group D (Lancefield) *beta*-hæmolytic streptococci and the minute members of group G *beta*-hæmolytic streptococci. This

probably means that a more scientific classification of the infecting streptococcus before administration of the drug would probably ensure better clinical results. It is, however, beyond dispute that if after proper bacteriological examination the correct dosage and method of administration be followed, the drug would be found to be specific in certain bacterial infections. Lastly, it must be remembered that though the drug holds out promise of great usefulness, caution should be observed with its treatment and, even if no serious toxic effect be noticed, it is advisable that the patient should be kept under close careful medical observation.

THE PHYSIOLOGY OF THE INDIVIDUAL IN THE TROPICS*

Part I

By R. N. CHOPRA, C.I.E., M.A., M.D., Sc.D., M.R.C.P.
 BREVET-COLONEL, I.M.S.

Honorary Physician to the King

Director, Calcutta School of Tropical Medicine

THOUGH physiology in its widest sense signifies the study of the phenomena presented by all living organisms, its chief interest is centred round the body of man. It should therefore be the objective of human physiology to study the so-called 'normal' human individual, since it provides an essential base line for the study of disease. Unfortunately, however, in this particular branch 'physiology' in spite of all its developments has made but little progress in recent years. The definition of 'normal' and the criteria of what constitutes the normal are still an open question. There has been a tendency among physiologists to lay stress on individual organs and tissues—on single bricks' composing the edifice—and not on the individual as a whole. As the human individual cannot exist uninfluenced by his external environment and as the environment is

variable the question of normality of the individual becomes relative, and has to be studied under the varying conditions of the altered and continually altering environments to which the individual must necessarily be subjected in different parts of the globe. In choosing the subject of '*The physiology of the individual in the tropics*', I had two objects in view. In the first place, I was anxious to select a subject which would be of interest to physiologists as well as to the medical profession in India; in the second place, I choose it as a subject which is of fundamental importance, but which has suffered from comparative neglect in modern medical thought.

THE INDIVIDUAL AND HIS ENVIRONMENT

Historical.—The study of the individual in relation to his environment has recently engaged the attention of many a physiologist and clinician though the problem is by no means a new one. In the earliest days of medicine in India centuries before the Christian era, the Hindu physician Charaka drew attention to the effects of different 'airs' and places on mankind. He prescribed special diet for particular seasons of the year, recommending one type of food for the summer and another for the winter. In the early dawn of Greek medicine Hippocrates recognized not only the significance of a 'change of winds' but also its physiological implications. After considering the effects on the embryo and the adult, he concluded that the races of mankind and types of animals were altered, as a result of the environment—and in this the 'airs, waters, and places' played a part. The Hippocratic recognition of the association between meteorological conditions (airs) and disease came down through the Middle Ages and practically every writer on medicine and physiology from the 17th to the 19th century stressed in different ways the 'Integration of the macrocosmos (environment) with the microcosmos' (the human organism). The interest in this subject waned in the last quarter of the 19th century when the science of bacteriology made its beginning through the pioneer researches of Pasteur, Lister and others.

In the study of diseases, emphasis was laid more on the invading parasite than on the invaded individual. With the advent of the science of immunology, serotherapy and chemotherapy, the importance of environmental influence receded more and more into the background. Whilst the physiologists studied the changes produced in the system by alteration in temperature, bacteriologists tended in their first enthusiasm to disregard the physiological fluctuations and attempted to attribute every disease process to specific parasites.

The reaction to environment.—Though the interest of medicine at present is chiefly centred, and perhaps rightly, on infectious diseases, the study of environmental conditions is none the less important. Let us consider how the individual reacts to his surroundings. Two methods have been devised by the organism to meet the forces of the environment. It seeks to lessen the impact and to meet the shock by increasing the resistance, in an endeavour to prevent disturbances of its equilibrium. This is usually effected by diminishing the consumption of energy or, in other words, the organism becomes *less reactive*. This phenomenon of attempting to shield itself against invasion is exemplified in spore formation and in the various forms of encystment of lower organisms. In the higher organisms, the same reaction finds expression in the mechanism of hibernation, in the deposition of subcutaneous fat and in the development of the epidermis. The other alternative is that the organism becomes more *reactive* and, instead of resisting any force disturbing its equilibrium, seeks to attune its mechanisms of equilibration to such a degree that they swing in a rhythm with the environmental force. This is seen in the development of special mechanisms for the rapid mobilization of reserves, in the unusual acuity of receptors and not infrequently in the formation of special sense organs. Man, after all, is a living organism existing in his own particular environment and, being endowed like all living beings with powers of adaptation, he reacts to it in such ways as to produce, if possible within himself, ideal conditions for living under

varying environments. This adjustment must necessarily involve fundamental changes in the organism, and probably of resistance to disease. The history of man is not inaptly described as 'an endeavour first to adjust himself to his environment and later to control that environment itself'.

The mechanisms designed to meet the environmental demands and the selection by the organism of different methods for adaptation are manifold. We will consider them in more detail later. It is important to emphasize here that it is not enough to understand any one reaction to a single well-defined change in environment; the repercussions on other reactions must also be determined and the degree to which they affect the capacity of the individual to react to further environmental changes of a different type. Such knowledge is essential if the organism is to be understood as a unit. The problem is naturally complicated and raises many interesting enquiries.

THE INDIVIDUAL AND HIS PHYSIOLOGICAL EQUILIBRIUM

The external environment with the effects of which we are concerned is not in reality the one in which the body cells live. As is well known, though the external environment varies greatly, the internal one remains remarkably constant and this is achieved, firstly, by certain physical and chemical factors inherent in the saline fluids which constitute the internal environment—the '*milieu interne*' of Claude Bernard, and secondly, by certain bodily reactions designed to prevent abnormality. An outstanding example is the constant neutrality of the fluids which bathe the body cells where even a slight increase in the hydrogen-ion-concentration from 0.000,000,05 ($10^{-7} \times 5N$) to 0.000,000,1N ($10^{-6} N$) might produce a serious dislocation of the vital processes. To counteract any such disturbances, there is always an effort on the part of the organism to oppose any tendency to change. This is best seen in the rapid breathing associated with all forms of muscular exercise. A contracting muscle needs proportionately more oxygen than a quiescent one; this increased oxygen usage implies an increased blood supply which again involves an augmented blood flow through the lungs and consequent increased ventilation. Similarly, the response to a rise of body temperature sets in motion simultaneously a number of complex reactions which tend to oppose any threatened alteration.

The apparent physiological stability of a living being which is suggested by the constancy of such characteristics as heart rate at rest, body temperature, blood sugar level, reaction of the blood, blood volume, blood pressure and composition of alveolar air, is not due to a static condition, but is only made possible by the lability and close correlation of dynamic forces which are constantly being adjusted in response to nervous, chemical or physical stimuli arising within or at the surfaces of the body. The equilibrium thus attained is therefore of an oscillatory type and is the resultant of the interplay of unstable and variable functional activities which are constantly operating in the body. Thus, the carbon dioxide content of alveolar air is remarkably constant in any individual and is controlled by the depth of respiration, which in turn is regulated by the carbon dioxide content of arterial blood; the respiratory centre is so sensitive that it will respond to changes which cannot be easily measured by chemical or physical methods. The high degree of sensitivity maintains the equilibrium without demonstrable oscillation but the oscillatory nature of the equilibrium may be unmasked and become recognizable in certain diseases as Cheyne-Stokes or other types of periodic breathing.

The temperature of the body is maintained fairly constant in health, despite variations in external temperature and activity, but during illness or during recovery from illness there may be a lack of sensitivity or some degree of failure of the regulating mechanism and the least exertion may cause an abnormal rise of temperature producing profuse sweating with a temporary fall of temperature below normal. Similar examples showing the oscillatory nature of physiological equilibrium might be taken from circulatory

adjustments, muscular co-ordination or from the regulation of blood-sugar level.

The range of reactivity and the limits of adaptability.—Interference with or destruction of these compensatory mechanisms will reduce the chance of recovery from accidents or diseases in which their activities are required to counteract the disturbance. A given compensatory mechanism may be adequate to maintain, under resting conditions, a physiological equilibrium within normal limits, so that the effect is not recognized until the mechanism is subjected to some stress. Thus, two individuals may have the same heart rate under the same resting conditions, but if the vagal impulses in both are eliminated by the injection of atropine, it may be found that the heart rate of one considerably exceeds that of the other. The heart rate is controlled by two opposing forces, one from the vagus and the other from the sympathetic, and although the net result of these may be the same in both before the injection of atropine, yet in the one a greater amount of nervous stimulation takes place than in the other. Again the fasting blood sugar level in two individuals may be identical and yet the injection of the same amount of adrenalin into each may cause in the one a much greater rise in blood sugar than in the other. Insulin will be less effective in the former than in the latter, suggesting that the self-adjusting mechanism in the one case is 'set' at a different level from that in the other, although the controlling factors in each case are so balanced that the equilibrium points are the same. Neither heart-rate nor blood sugar level *per se* therefore gives any clue to the reserve powers of the complex systems which control these physiological characteristics. Hence the test of physiological normality is relative and is not solely or even mainly the equilibrium point of the various compensatory systems. In fact, the extent to which these systems will respond, when brought into play by adverse changes in the environment of the individual, and the degree of their response are measures of the organism's reserve capacity or power of adaptation. On this reserve power depends the success of the individual in his adaptation or acclimatization to changed surroundings and environments.

ENVIRONMENT AND THE MECHANISM OF ADAPTATION

Physiological factors in adaptation.—Adaptation has been aptly defined as the continuous adjustment of internal relations to external relations. The ability to respond actively to changes in environment is an essential characteristic of any organism. The range of environmental adaptation of even the most primitive cell is relatively wide, although the mechanism of response may be simple; but as we advance in the scale of animal life, the range of adaptation becomes even greater as the mechanism and the means of adjustment become more complex. Thus the single-cell organism existing in a relatively stable fluid environment needs only direct adjustment to the environment and this adjustment must of necessity be a 'chemical' one. This is exemplified in the behaviour of the protoplasm of the *myxomycetes* which, when placed on a piece of blotting paper, will crawl towards an infusion of dead leaves or away from a solution of quinine. The amoeba again can respond only to changes in the composition of the fluid in its immediate vicinity. When multicellular organisms begin to specialize, this comparatively simple chemical adjustment is not found adequate and special methods have to be elaborated, by which a 'colony' type of life can be perpetuated. Individual cells of multicellular organisms begin to manufacture substances through which the different members of a cellular unit can be influenced. These substances or 'hormones' circulate in the fluids of the body, and play an extensive rôle in *hormonic* adjustment to environment. Their primary purpose is to initiate automatic reactions and to sensitize the tissues to react either more rapidly or more slowly. The higher we ascend in the animal scale, the means by which the organism responds to environmental changes become more varied and complex, and an additional mechanism of adjustment other than chemical and hormonal is

called for. For this purpose, the anatomically-defined autonomic nervous system, both sympathetic and parasympathetic, has been developed. Finally, when the level is reached at which reason is developed, not only are accomplished changes appreciated but the possibility of alteration, made or threatened, can be recognized and guarded against; in other words, the adaptive reactions become conscious and adjustment to meet them 'volitional'. Thus, among higher animals the distance receptors (eye, ear, nose) give warning of approaching danger, while in man complex mental processes allow the possibility of altered environment to be inferred, although the actual change may not be imminent. All the reactions of a biologic mechanism to environment may therefore be said to be mediated through three distinct but mutually-related and integrated processes—chemical, endocrinal and nervous. The three components are functionally inseparable, and no one component can be disturbed without disturbing the others.

Reserve forces of the organism.—A living organism, whether a single cell or an integrated cell mass (the individual), may therefore be regarded as a highly unstable system, which tends to reproduce itself continuously under the average of conditions to which it is subject, but undergoes disintegration as a result of any variation from this average. The ability to maintain an equilibrium without the breakdown of the adaptive mechanism under adverse conditions determines the development of the individual and ultimately of the species. The greater the possibility of protective reaction the greater are the chances of survival. It seems important therefore to stress the fact that the animal body, although often compared with a man-made engine, differs fundamentally from the latter in that it has latent reserve forces capable of adjusting the animal to a new environment, in other words it possesses powers of adaptability. These forces call forth hypertrophy of glands and tissues in response to appropriate stimuli and even carry out repair of damaged parts. Sensibility or facility of response can be improved by frequent usage or 'training', as in the case of muscular exercise. The athlete can undertake a given amount of exercise with less disturbance of respiration and circulation than can the untrained person, and his return to the resting normal condition is also quicker. Unlike a test tube, in which chemical reactions are definitely limited, the efficiency of practically all the compensatory systems of the body can be increased by judicious use if the stimulus producing the reaction is adequate in each case.

THE INDIVIDUAL AND HIS ATMOSPHERIC ENVIRONMENT

The most important environmental factor is the atmosphere in which we live. Hippocrates, who may be called the father of the modern science of climatology, recognized the importance of 'airs' over 'waters' and 'places' and also appreciated the different qualities of the cold and the tropical atmospheres and other cosmic influences. As the atmospheric environment is so familiar, we fail to recognize the importance of the part it plays in moulding the physiology and sometimes the pathology of 'air-living' animals. We are likely to forget that we take in as much air by weight per day as we do of food.

The atmosphere or the air-mass surrounding the earth is not stable but fluctuates from place to place and from time to time, particularly with the 'cyclonic' waves. These fluctuations and atmospheric disturbances are normal and necessary sequences to temperature differences on the earth's surface. It is not my purpose here to examine these meteorological disturbances in detail; I only wish to draw attention to the influences which such an unstable and ever-changing aerial environment exerts on different phases of human activity—physical, mental, social, economic—and on racial development and retrogression.

Climate and climatic factors.—The term 'climate' has been defined as the combined effects of the sun, the atmosphere and the earth upon living objects at any one place on the earth's surface. Climate primarily results from the effects on the earth's surface of the incident solar energy and its unequal distribution. For

descriptive purposes it is usually stated in terms which have reference to the so-called *climatic elements*—namely the temperature of the air, its humidity, also the amount of precipitation of rain, snow, frost, its motion, density, transparency and electrification. The climatic elements are dependent on physiographic factors, such as distribution of land and water, mountain ranges, nature of soil, distance from the equator and height above the sea level. The latitude and the altitude are, however, the most important and deserve special attention.

The words 'climate' and 'weather' are often used synonymously in common parlance but 'weather' means those atmospheric elements we see, feel or observe at a particular time or specified period, while climate means the aggregate of weather conditions. In cold and temperate latitudes, the weather becomes a more outstanding feature than the climate itself. In the tropics, for the greater part of the year, the climate becomes a succession of equal combinations of meteorological elements, the annual range of which seldom exceeds the diurnal range. The 'weather' in the tropics therefore is practically the same as the 'climate'. The monotony of the tropical climate is a characteristic not seen in the temperate or cold regions of the globe.

Climate in the tropics.—It is generally assumed that the climates of the whole of the tropical zone are in all respects alike and therefore the term 'tropical climate' is often used, though incorrectly. Climatologists have divided the tropical belt into several subdivisions according to the situation of the land in relation to the equator, the vicinity of water, the growth of vegetation, the presence of mountains or hills, the proximity of land to oceanic currents and trade winds, and its height above the sea level. All these factors will naturally influence the 'climatic type' of a locality. Thus the tropical zone includes deserts, damp forests, jungles, swamp lands and fertile islands refreshed by cool steady winds from the ocean, low-lying plains and valleys under the influence of the periodic monsoons, and mountains several thousand feet above sea level. All these regions are not equally disagreeable for the residents. The deserts, for example, are free from many tropical diseases, for their parched soil and dry, sterile air are unfavourable to the development and distribution of most micro-organisms and disease-bearing insects. On the other hand, the dust, heat and brilliant sunshine are very trying, and the paucity of water is obviously a serious limitation. Again, wherever mountains and plateaux occur in the tropics, the climatic conditions are distinctly different from that in the plains and may be actually mild and agreeable. It will therefore be seen that, within the tropical zone, there may be areas with peculiar climatic types with their special advantages and disadvantages. In dealing with climate in the tropics, I shall confine myself to the consideration of its effects in tropical plains in the latitudes near the equator.

The climate in these regions varies but little and the temperature ranges between 75°F. (25°C.) to about 115°F. (46°C.). There are no seasons in the tropical zone and monthly and diurnal variations of temperature are slight. These areas are often subject to the influence of monsoon with their alternate dry and wet spells. They are usually very fertile and support a variety of luxuriant vegetation. The study of the climates prevailing in this zone has attracted most attention because these areas have been frequently colonized by the white race. A large portion of the plains of India has a climate of this type and therefore it is of very great interest to us to know the physiological adjustments required of human beings in such a climate.

CLIMATE AND THE INDIVIDUAL

The influence of climate on man is so well recognized that it is often the main topic of daily conversation. One often hears of a 'bracing' climate or a 'relaxing' climate, and the beneficial effect of climate variation finds its expression in our desire for a 'change of air'. Though we do not know whether and to what extent actual temperature, or humidity or wind affects human beings, there appears to be a direct

relationship between the physical and mental vitality and the variability of climates. Huntington in his fascinating book on 'Civilization and Climate' puts forward the theory that all the world's great civilizations are now in regions experiencing often unexpected changes of weather and that the superiority of races inhabiting temperate regions of the globe is largely the result of climatic influences. Man is considered a mere creature of his meteorological environment and climate is said to rule the destinies of nations. Mills (1934 to 1936) has corroborated some of Huntington's conclusions. According to him, there are energy differences between the races living in warm climates and those in temperate climates which cannot be accounted for on the basis of diet and mode of living alone. The tropical person has a lower oxygen consumption, a lower blood pressure and a lower capacity to meet emergencies than the resident of temperate zones. Some psychologists maintain that each climate tends to develop its own characteristic mentality. In other words, climate not only modifies the physical features but also the nervous system of the individual. These and other similar questions raise interesting issues which are not easily answered. Because of the difficulty involved in the study of the direct effects of climate on the individual, the data recorded in the literature are very discordant. There is a school of thought which maintains that too much stress is laid on climatic factors by Huntington and Mills and that many of their generalizations probably are not based on a rigidly scientific and critical evaluation of the facts. While it is not possible in the present state of our knowledge to give any definite opinion, there appears to be little doubt that climate plays an important rôle, though often an indirect and subtle one, in the production of many physiological changes in the organism and as a predisposing cause or an accessory cause in many disease processes. I propose to examine some of these changes in the subsequent sections. It will suffice here to indicate that though man can live in any region where food and water can be obtained, he can best develop his physical and mental capabilities under the most favourable environmental conditions. There seems but little doubt that there is also a distinct optimum condition for man, just as for plants and animals, and any departure from it adversely affects the organism.

EFFECTS OF HEAT AND SUNLIGHT IN THE TROPICS

In considering the effects of residence in tropical climates, attention is at once directed to three major environmental factors, *viz.* temperature, humidity and sunlight. There are a number of other climatic and environmental factors, such as wind movement, atmospheric electricity, ionization, etc., which also affect the human organism, though the responses elicited do not leave lasting impressions on the individual. In nature, all these climatic factors operate simultaneously and the reactionary changes observed at any one time are in most cases a summation effect, one factor being superimposed on the other. Thus while the acute effects of encountering very high temperatures as of a heat wave in a desert region may be tolerated without harm, the organism may show signs of intolerance or breakdown when excessive humidity is superimposed on such a high environmental temperature. This interdependence of several climatic factors makes the analysis of the effects on the individual of the different components which constitute the 'climatic drive' a difficult matter and is mainly responsible for many of the conflicting views which have been expressed. Let us consider each of these factors separately and see to what extent each component contributes to produce the resultant total effects.

Sunlight.—The biological effect of sunlight has received perhaps more attention than any other factor in this group. A careful perusal of the literature has convinced me that the knowledge gained in this branch is indefinite and unsatisfactory. The beneficial results obtained by ultraviolet treatment of tuberculosis and the effects of ultraviolet treatment of rickets created the impression that the ultra-violet portion of the spectrum was the important factor responsible for the biological

effects produced. Several investigators in the tropical belts of Australia, the Philippines and the Netherlands East Indies have adduced experimental evidence indicating that the ultra-violet light, being non-absorbable by the skin, is probably much less important than the infra-red and the visible-red end of the spectrum, which penetrates the superficial layers of the skin and is perceived by the organism as heat energy. Whatever direct effects tropical sunlight may have have therefore been attributed to its thermal action. Petersen (1936) has, however, shown that ultra-violet rays may produce physiological effects by first sensitizing the skin and then inducing a reflex stimulation of the thyroid and other glands of internal secretion. It is difficult in the present state of knowledge to evaluate the evidence with regard to the part played by the different components of the spectrum in producing physiological reactions in the individual.

Humidity.—The effect of humidity on the human organism has recently engaged the attention of public health authorities and sanitary engineers interested in environmental control through air-conditioning methods. That humidity modifies, to a great extent, the effects of heat is generally recognized. A moist humid atmosphere is associated with depression and discomfort, and, conversely, dry air, irrespective of its temperature, induces a feeling of comfort and well-being. The water content of the atmosphere must affect the water content of the body. In the regions of high environmental temperature, such as are met with in the plains of India for example, greater humidity will prevent proper evaporation and heat loss with resulting disturbance in the respiratory exchange, in the carbon dioxide content of the blood, and consequently in the water and ion balance. It may therefore be stated that high humidity, by diminishing evaporation of sweat, merely aids in increasing the effects of heat, but as a direct factor it does not appear to possess any great specific importance.

Temperature.—Studies on the changes produced in the body of man as a result of exposure to high environmental temperature have been numerous, but, like most aspects of tropical physiology, the data are conflicting. It has been reported that a change in the environmental temperature produces a change in the *body temperature* of the individual and that in the tropics body temperature may be permanently above the average in the temperate zones. Though a large amount of work done both in man and in experimental animals has since been published, the position is still undecided. While it is true that a change in the body temperature of an individual may be easily effected for brief periods by exposure to high external temperatures, it is doubtful if, in view of the sensitive heat-regulating mechanism in man, a permanent change can be brought about by prolonged exposure such as residence in the tropics. The same argument may be adduced against the contention of some workers that the *skin temperature* is raised in tropical zones. From physiological considerations, it is logical to assume that the flushing of the skin, as a result of exposure to a hot environment, raises the skin temperature, but the temperature soon drops when perspiration breaks out. It has also been suggested that darker coloured individuals in the tropics possess a higher skin temperature than the light coloured ones. The statement also has not been confirmed.

Regulation of body temperature.—The chief climatic factor affecting the individual in the tropics being the high environmental temperature, the adaptation that he is called upon to make is naturally one of heat regulation. This is accomplished by a fine balance between *heat production* and *heat dissipation*. Heat is always produced in the body by the metabolic activities of the protoplasm and, if life and the power of work of the individual are to be maintained, this heat production cannot be reduced below a certain minimum. Hence, heat regulation of the individual is more often effected through modifications of the various mechanisms available for heat loss, than through changes in heat production.

Heat loss and rôle of pigment.—It was generally recognized that tropical races are at an advantage over

the European settlers in the matter of heat dissipation. The possibility suggested itself that acclimatization for generations in a climate where the mechanism of heat loss had to operate under excessive strain might have endowed the skin of the tropical races with an additional power and facility in getting rid of excess heat by the processes of physical heat regulation—conduction, convection, radiation and evaporation—at a more rapid rate than individuals from cooler zones. It has been claimed that the skin of tropical races loses heat by convection more rapidly than the skin of white races but these conclusions have not been universally accepted. The suggestion next put forward was that the dark skin radiated heat more quickly than the white skin, but satisfactory evidence has not been obtained in favour of this contention. It is therefore difficult to state with any degree of certainty whether the presence of pigment in the skin confers any real advantage so far as heat loss by *radiation* is concerned. There is however little doubt that pigment plays an important part in heat regulation in other ways. Owing to the high absorption coefficient of melanin, heat is rapidly produced in the skin, this stimulates the local heat receptors with consequent reflex sweating. Moreover, pigmentation of the skin is necessary to protect the deeper structures from the injurious effect of sunlight and to protect the sensitive cutaneous nerve endings from irritation. The brown-skinned races in the tropics, by virtue of the pigment, have apparently developed a more sensitive cutaneous heat-regulating mechanism, and they can cool off more rapidly by reason of the early formation of a fine layer of sweat drops. It is generally admitted that Europeans who tend to take on pigmentation are on the whole better acclimatized to the tropics than those who do not darken. The studies of Acton in the School of Tropical Medicine on the pigments of the normal skin of Europeans and Indians are of interest in this connection. He found that the pigments present in the basal cell layer of the epidermis of the two groups did not differ in the actual amount (quantity) but in their chemical composition (quality). The pigment present in the Indian skin was deeper brown in colour and showed a distinct tendency to increased chemical reaction with 'dopa-oxydase'. The significance of this is not yet clear. The precursor of melanin is dihydroxyphenylamine which is again a breakdown product of the amino-acid tyrosin. It is possible that the differences in the diet and metabolic rates in the natural tropical inhabitants might be ultimately associated with the production of a chemically-distinct type of pigment in the skin. The distribution of pigment may also play a part in bringing about the adaptation which the tropical inhabitants are supposed to possess. Thus, in negroes, histological evidence shows that pigmentation is deeper and more diffusely spread than in the white races where the pigment is contained chiefly in the Malpighian layer and in the superficial layers of the corium.

Sweat secretion.—For physical heat regulation, however, the activity of the sweat glands is of outstanding importance. Their efficiency depends on several factors: (1) humidity of the environmental air, (2) concentration of sweat glands per unit area, and (3) the degree of activity of these glands. Humidity, though it is important, because on it depends the evaporation of water from the skin, does not in actual practice exert a great influence, because apparently high degrees of humidity, provided they fall short of absolute saturation, can be borne by the system with impunity. The concentration of sweat glands in the skin may regulate the amount of perspiration, and it was believed by many early workers that the better heat-tolerance of the dark-skinned races was probably due to this factor. Though some investigators have reported a greater concentration of sweat glands per unit area of skin surface among them, these findings have not been corroborated. From the point of view of heat loss, increased concentration of sweat glands cannot be considered specially significant as the quantitative outpouring of sweat is less important than its distribution on the skin to form an even film, which leads to rapid evaporation.

Composition of sweat.—A study of the composition of sweat produced in extreme dry heat shows that there is an adaptive response on the part of the organism and that the concentration of salt in sweat decreases after the first few days in the hot environment. To cite a concrete example, the amount of sweat produced with ordinary type of work in a climate such as that of Calcutta (95° to 105°F. or 35° to 41°C.) may be as much as 7 litres during the day. Assuming a sodium chloride concentration of 0.3 per cent, this means a loss of 22.5 gm. of salt. Man's daily intake of sodium chloride is 10 to 15 gm. and since the average normal excretion of salt in the urine is in the neighbourhood of 12 gm. in 24 hours, the degree to which muscular work in such a climate may deplete body chlorides is remarkable. If this depletion is not compensated, the

normal acid-base equilibrium of the body fluids is apt to be seriously disturbed and heat cramps from loss of salt may supervene. It seems clear that some sort of adaptation takes place in normal healthy individuals. Little is known, however, of the nature of this adaptation, though it has been noted that all men sweat more readily as they get accustomed to exposure to heat. This increased 'ability to perspire' is known to be one of the few definite adaptations to high temperature and it is interesting to note that it is a case of 'controlled' rather than profuse wasteful sweating. The sweat secreted is said to contain an unusually low concentration of sodium chloride and this would appear to be an attempt at conservation of chlorides, as even on a high chloride intake their concentration remains low.

(To be concluded in the next issue)

Medical News

FIFTEENTH ALL-INDIA MEDICAL RESEARCH WORKERS' CONFERENCE

The Viceroy's address

THIS conference of research workers has been held each year during the last fifteen years. On each of the previous occasions it has been held at the Calcutta School of Tropical Medicine. As His Excellency the Viceroy had kindly promised to open the conference, and for other reasons, this year it was decided to hold it at the Imperial capital. There were over a hundred delegates at the conference; each Indian province was represented, usually by more than one delegate; delegates were also sent by Burma, the railway department, and the defence department; and there were a number of visitors including representatives of the Rockefeller Foundation and the London School of Tropical Medicine.

His Excellency the Viceroy opened the conference on Monday, 29th November. He said:—

'Medical research is a matter in which I have always taken the keenest personal interest and I had, for some time up to the date of my assumption of office as Viceroy, the honour of presiding as chairman over the Medical Research Council of the Privy Council.

'It is, in these circumstances, a source of peculiar pleasure to me to see you here to-day and to be able to pay a tribute, in person, to the invaluable work which has been done, over so long a period, by the Indian Research Fund Association and the bodies connected with it and by the research workers whom you, ladies and gentlemen, represent to-day.

'The advance in the organization and development of medical research in India has been particularly marked in the last 25 years. In 1911 the Indian Research Fund Association was established, and although the years of war, which followed, interrupted the work which it was designed to further, the foundations had been laid and, on the conclusion of the war, the opportunity was taken for development in many important directions.

'In 1920 the School of Tropical Medicine at Calcutta, the necessity of which had so long been realized, was established largely through the efforts and enthusiasm of Sir Leonard Rogers.

Health research

'In 1932 the munificence of the Rockefeller Foundation made it possible to establish the All-India Institute of Hygiene and Public Health, a centre at which provision has been made for research, which has been actively pursued on the subjects of nutrition, and malaria and cholera, since 1921.

'The research workers have annually met in conference, a conference attended not only by senior officers of the medical and public health departments of the Central and Provincial Governments, but by other research workers from all parts of India. I cannot over-estimate the importance which, in my judgment, attaches to an occasion such as this for the interchange of

views and the free discussion of questions of fundamental importance by experts of recognized eminence and distinction in their respective fields.

'It will not be possible for me to-day in the brief time at my disposal to do more than touch on two or three aspects of the work of medical research at the present time.

Help from the public

'Before I proceed to mention certain individual items in which I take a particularly close interest, I would like of say briefly how great is the importance from the point of view of India that attaches to the close and earnest pursuit of the solution of the many problems which still lie before us in the field of medical research, and how strong is the case for the generous support of philanthropists in this country in providing financial assistance for activities, the outcome of which is of such great significance to the whole of this sub-continent.

Tropical research

'The School of Tropical Medicine at Calcutta, the work of which has been so invaluable, is fortunate in having a large endowment fund, which was raised from donations from commercial associations and firms principally in Bengal and Assam, such as the Indian Tea Association and the Indian Jute Association. No one, who is aware of the invaluable results which have emerged from the work and the researches of the School of Tropical Medicine and its officers, can for a moment hesitate as to the value which has been obtained for the money which the bodies in question with such public spirit provided in aid of research.

'The All-India Institute of Hygiene and Public Health, the work of which again is so material to the maintenance of health and the reduction of the incidence of mortality in India, is the result of a private munificence, but of private munificence from a source outside this country. The appeal I would make is to those private individuals who have the welfare and the improvement of standards of health in this country at heart to bear in mind the strong claims of medical research in its various forms to their munificence. There is no way, I am sure, in which a more real and valuable contribution can be made to progress in India and I can most warmly commend the claims of medical research to consideration in this connexion.

'There are one or two problems on which I would like to say a word to-day in regard to the work which has been performed by medical research in India on malarial fevers, the reduction of maternal and infant mortality, and the ever-growing and most important problem of tuberculosis.

'We are all of us familiar with the immense significance of the problem of malaria particularly in rural areas and we can, I think, contemplate with satisfaction the admirable work which has been done during the last few years by the Malaria Survey of India.

'As some of you may know, when I assumed office I found that the threat of malaria to the health of Delhi, new and old, was rapidly developing into a serious menace and last year and this year the Malaria Survey has in the Delhi area undertaken detailed and extensive anti-malaria schemes. The actual work is carried out by the public works departments.

Delhi experiment

'The development of these schemes which I have inspected on various occasions has given me the opportunity of satisfying myself over a long period of months in Indian conditions as to the extent to which prophylactic measures can with profit and with the certainty of success be undertaken, and I am glad to say that the schemes, which have been initiated and which have been developed so successfully in and round Delhi, show now, more than a year after they had first been undertaken, results which entitle us to feel confident that the growing threat of malaria in this very important area will be brought under control if not altogether eliminated.

'What has been done in Delhi can be done elsewhere, and I would commend to malaria-stricken areas the work of the Malaria Survey and the example afforded by the success of the operations which have been undertaken in Delhi.

Cholera prevention

'Much remains to be done in connection with cholera research, a question which has always been considered of international importance and on which the Permanent Committee of the Office Internationale d'Hygiene Publique asked some years ago for the assistance of the Government of India. The assistance was, I need not say, readily accorded and I am glad to think that the Office Internationale has on several occasions expressed its warm appreciation of the admirable results which have been obtained by a number of different laboratories and workers in India under the co-ordinating superintendence of Colonel Taylor, the Director of the Central Research Institute at Kasauli.

'There is great hope that the investigations now proceeding will eventually solve many of the difficulties associated with the control and prevention of this disease.

Nutrition problem

'You are well aware of the interest I take in the matter of nutrition research and in this very important question India, thanks mainly to the work of Sir Robert McCarrison, can claim an eminent place. Nutrition and immunity, as an eminent authority has pointed out, constitute the two most powerful weapons in man's hand for his fight against disease. Adequate nutrition has a positive contribution to make to the health and the sense of well-being of the individual. The subject is, I am well aware, one of extreme complexity in this country, because the problem of nutrition is so closely associated with the economic condition of the people and because of the poverty which to the profound regret of all of us prevails in so many parts of India.

'Any attempts for the improvement of the position must, therefore, take note of the existing food resources of the country and must devise means for their augmentation.

Lack of knowledge

'A difficulty too, the importance of which will not be overlooked, is that in regard to a large section of the population a lack of knowledge as to the modern dietetic principles may frequently prevent them from utilizing even the available resources to the fullest possible extent.

'I fully realize that this is a problem which is fundamentally one for Provincial Governments and local authorities, but I am sure that those Governments and those local authorities can look with confidence to the Indian Research Fund Association to assist them by carrying out such research as may be essential for

formulating administrative policy, and I would refer in particular in this connection to the invaluable work which has been performed by the Nutrition Research Laboratories of the Association at Coonoor.

'As you are aware, those laboratories have applied themselves for years past to nutrition research, to the study of the diets of the different communities in India and to deal with specific nutritional diseases.

Dietetic surveys

'I am glad to think that under Dr. Aykroyd's expert guidance, within the last year or two, the scope of this work has been considerably increased and that it now includes dietetic surveys on an extended scale in different parts of India, the assessment of the nutritive value of articles of food in common use by the people, the formulation of objective standards for nutrition and the dissemination of knowledge regarding nutrition by free advice to institutions and by propaganda.

'Facilities have also been made available for selected officers from provincial departments of public health to undergo a special course of nutritional training at Coonoor—a course, the value of which, I am convinced, is great.

Training at Coonoor

'It is my earnest hope that those provinces which, owing to pressure on the existing personnel or for other reasons, were unable to depute officers to the first course of this nature will find it possible to take advantage of a further course which is now proposed to be held. I am convinced myself of the importance of providing trained officers for the provinces, who can be employed in the nutritional field, and I am confident that the fullest use will be made in that field by the Provincial Governments which have found themselves able in the past, or which may find themselves able in the future, to depute officers to Coonoor of the expert training which their officers have received there.

Co-ordination need

'A further step of substantial importance is that, consequent on a recommendation of the Nutrition Advisory Committee, steps are now being taken to co-ordinate agricultural research with the needs of human nutrition. The problems of human nutrition are closely associated with those of agriculture and of animal husbandry and it is, in my judgment, a matter of the utmost importance that this association should be adequately recognized in terms of the organization of research.

Milk for children

'Let me refer briefly in this connection to one side issue, for though it is a side issue it is one of much significance and one to which I have endeavoured in the past to draw particular attention. I refer to the benefit to be derived by the feeding of children even with small quantities of milk, a benefit which has been more than established by the work of the Nutrition Research Laboratories at Coonoor.

'The results of those experiments, or to take one instance only, the effect of giving skimmed milk regularly to day and boarding school children, are remarkable indeed. When an ill-nourished child living on rice is given milk regularly it immediately begins to grow more rapidly and its general health shows an improvement.

'I fully realize that milk costs money and that the resources at our disposal are insufficient to enable us to go as far as we should like in this regard.

'To supply a child daily with eight ounces of liquid milk reconstituted from skimmed milk powder costs about 12 annas a month, a large sum in relation to living standards in India. Nevertheless, I am glad to see that a number of children's institutions have, by economies in other directions, managed to include greater quantities of milk in their diet schedules and I would like again to draw such attention as I may to the great importance of the use of milk and to its beneficent result on the younger generation and so on the future of India.

THE SECOND EUROPEAN CONGRESS OF PLASTIC SURGERY

THE European Society of Structive Surgery held its Second Congress in the Barnes Hall of the Royal Society of Medicine, No. 1, Wimpole Street, London, under the Presidency of Mr. T. Pomfret Kilner, on the 6th and 7th October, 1937. Delegates from most of the countries in Europe participated in the Congress. The President, in welcoming the delegates, hoped that the discussions during the Congress would greatly add to the advancement of plastic surgery. Sir Harold Gillies, the President of Honour, opened the Congress and Professor Clairmont (Zurich), the Vice-President of Honour, wished the Congress every success.

The subjects for discussion were divided into three sections:—

- (1) Free skin grafts,
- (2) The restoration of nasal contour, and
- (3) Mammoplasty procedures.

Under each of these sections, there were opening papers and short communications devoted to special points in technique, followed by discussion and replies by earlier speakers.

On the morning of the first day, Dr. M. Coelst (Brussels), Dr. L. Dufourmontel (Paris), Dr. G. Sanvenero Rosselli (Milan) and Dr. F. Burian (Prague) presented opening papers on free and full thickness skin grafts. Professor Clairmont and Mr. G. Humby (London) presented short communications.

In the afternoon, Dr. Sanvenero Rosselli, Mr. A. R. Mowlem (London) and Sir Harold Gillies (London) contributed opening papers on restoration of nasal contour. Sir Harold Gillies' communication on his modification of restoration of nasal contour by intra-nasal skin grafts, illustrated by a coloured film, was very much appreciated. Mr. Mowlem's paper on 'Bone grafts in the restoration of nasal contour' and Dr. J. Thavanin's paper on 'Causes of intolerance of cartilage grafts' were interesting. Dr. J. Safian of New York spoke on 'An evaluation of rhinoplasty'.

The afternoon of the second day was devoted to mammoplasty procedures. Dr. F. Burian's paper on 'Our principles of mammoplasty' was read by Dr. Eva Kubertova. Mr. A. H. MacIndoe (London) reviewed on 80 cases of mammoplasty. A film showing Dr. M. J. De Lara's (Havana) method of mammoplasty was shown. Professor Essen, Professor Clairmont and Sir Harold Gillies took part in very interesting discussions throughout the Congress.

The delegates dined with the President and the President of Honour at the Langham Hotel on the night of the 7th October.

Operations were arranged on Friday at St. Andrew's Hospital, Dollis Hill, London, to demonstrate the various procedures discussed at the Congress. Dr. M. Coelst demonstrated his full thickness skin graft and his special method of dressing. Sir Harold Gillies grafted maternal ear cartilage to the child, and Mr. Kilner demonstrated the Eastern method of skin grafting in a case of ectropion.

THE IDEAL CHAPATTI

NUTRITION RESEARCH: ONE ANNA RECIPE

A RECIPE for a nutritious *chapatti* suitable for out-door workers in India, has been evolved by the Nutrition Research Laboratories at Coonoor.

A manual labourer needs at least two good meals a day. It is often impossible for him to return home to consume his midday meal and he cannot afford to eat in a hotel even if one were available.

The meal, therefore, which he takes with him, should be sufficient in quantity and well-balanced, that is, it should contain the essential nutritive elements in correct proportions. It should be cheap, made of easily obtainable foods, and be simple to prepare. It should be easy to carry, that is, it should be solid to avoid the possibility of spilling, small in bulk, and not require a special utensil to contain it, and should also remain fresh and palatable for a number of hours.

THE INGREDIENTS

Such a *missi chapatti* fulfilling all these conditions may be made from the following ingredients:—

Whole-wheat flour—10 oz. or 5 *chataks*, Bengal gram flour—2½ oz. or 1½ *chataks*, onions—¾ oz. or ¾ *chatak*, Fenugreek leaves (or any other green edible leaves)—½ oz. or ¼ *chatak*, milk—1 oz. or ½ *chatak*, salt—½ oz. or ¼ *chatak*, and ghee or butter—¼ oz. or ¼ *chatak*.

These constituents, except ghee, are mixed, water being added and the whole kneaded into a dough. *Chapattis* are made from the dough in the ordinary way, good thick *chapattis* being recommended, since these remain fresh longer than the thin ones. Subsequently ghee is smeared on the *chapattis*.

The weight of this meal is about 1 lb. or half a seer; it will supply about 1,300 to 1,400 calories, which is approximately half the daily requirement of a labourer, and about 50 grammes of protein. The mixture contained in the *chapatti* is rich in vitamin and mineral salts.

If fresh milk cannot be obtained, *khoa* or skimmed milk powder can be used. For those who can afford it, the addition of a greater quantity of milk or an egg to the dough is recommended.

Such a meal is easy to carry folded in a broad leaf or wrapped in paper. It remains fresh and palatable for a number of hours and can be eaten with no accessories except water. Its cost is about 1 anna. It can be recommended for travellers and for picnic parties, as well as for out-door labourers.

DR. JOSEPH BENJAMIN PRIZE AND DR. P. S. RAMACHANDRIAR PRIZE

NOTICE is hereby given that the subject for the Dr. Joseph Benjamin prize of the value of Rs. 35 (rupees thirty-five only) for the year 1937 is 'Puerperal sepsis: its cause, symptoms, treatment and prevention'; and for the Dr. P. S. Ramachandriar prize of the value of Rs. 25 (rupees twenty-five only) for the year 1937 is 'Cholera: its prevention, causes, symptoms and treatment'.

1. All *bona-fide* members of the All-India Medical Licentiate's Association can compete.

2. Intending competitors are requested to write papers from practical points and in lecture style and the same should not exceed 1,000 typed lines or their equivalent.

3. The papers should be sent to Dr. Jamintram B. Desai, President, Gujrat Branch, All-India Medical Licentiate's Association, 52, Pritamnagar, Ellis Bridge, Ahmedabad, so as to reach him on or before the 31st March, 1938.

P. S. TRIVEDI.

Secretary, Gujrat Branch, Ahmedabad.

THE TINNEVELLY DISTRICT MEDICAL ASSOCIATION

THE Anniversary of the Tinnevely District Medical Association has been provisionally fixed for celebration on the penultimate Saturday in January 1938.

A medical exhibition will be held consisting of surgical goods, medical appliances, drugs, etc.

Firms who are interested are kindly requested to send in their representatives with articles. Stalls are given free.

All correspondence on the subject should be sent to the following address:—

Secretary, The Tinnevely District Medical Association, Palamcottah.

K. RAMA AYYAR,
Secretary and Treasurer.

A MALARIA CONTROL EXHIBITION

A MALARIA control conference and exhibition took place on the 15th and 16th November, 1937, at the All-India Institute of Hygiene and Public Health. The

object of this function was to remind the medical profession of the problems which malaria in all its aspects offers and how they may contribute their individual share towards malaria sanitation; it was arranged by the Scientific Department, 'Bayer', in co-operation with the All-India Institute of Hygiene and Public Health, the School of Tropical Medicine and the Bengal Health Department, Bengal, the Malaria Department, the Bengal Nagpur Railway, and the Zoological Survey of India.

The exhibition was formally opened by Dr. R. B. Lal, the Director of the All-India Institute of Hygiene. The exhibits were supplied by the Institute of Hygiene, the School of Tropical Medicine, and the Scientific Department, 'Bayer'. Further contributions were made by Dr. Mansou, the chief medical officer, Jorehaut Tea Co., Ltd., Cinnamara, Assam, and by Mr. R. Senior White, the malarialogist of the Bengal Nagpur Railway. The exhibition was composed in such a way as to give

by suitable plants as an effective measure in removing those vectors which breed in grassy-edged water exposed to sunlight, e.g., *A. minimus* in Assam and Eastern Bengal. A number of instructive pictures and models showed the various forms of drainage adapted to the topography of the land. Another part was devoted to the rôle of drugs, either alone or as a supplementary measure to larval control. The results of the Burdwan experiment over the last four years were given in graphs showing the fall in spleen rates, as well as the decrease in the number of sick days over these years. In this scheme plasmochin in small doses was added to every quinine treatment, in order to reduce the relapse rate and to interrupt the sexual cyclic development. Another set of graphs gave the recent experiment of Field and his co-workers, comparing the results of atabrin and quinine prophylaxis, with the author's conclusion that atabrin is superior to quinine, in so far as its effect on the

A corner of the exhibition.

an idea of the many and varied problems which are confronting malarialogists, and urge at the same time a combination of all measures if a maximum of success is to be achieved.

The section of the Institute of Hygiene showed the various anopheline vectors and the life-cycle of the parasites in man and mosquito indicating in which way this vicious cycle can be interrupted. It was demonstrated how an individual may protect himself against the bites of adult anophelines by mosquito nets, protective clothing, screening of houses (a method which has been used successfully in other malarious countries but is still not much in favour in India), repellents such as citronella oil, etc. Another section dealt exhaustively with the various anti-larval measures, i.e., by oiling and paris-greening. The natural enemies of larvæ, e.g., larvicidal fish (among which in Bengal *Panchax panchax* seems to be the most active larvæ-feeder), were shown as live specimens with corresponding pictures to facilitate identification. The rôle of aquatic plants in preventing breeding was demonstrated. Prominence was given to the shading of breeding places

frequency and severity of attacks and on the reappearance of attacks after the cessation of the prophylaxis is concerned. Amongst further materials the recent experiment of the same type carried out by Mosna and Canalis in Italy was also represented.

Various suggestions were given as to how anti-larval measures could be supported by drug prophylaxis in those months of the year in which in a given locality the infection rate among mosquitoes is as a rule at its highest.

In the clinical section a number of typical charts of malaria patients treated with atabrin from various tea gardens in Assam proved of special interest to the practitioners who attended.

The formal opening of the exhibition was followed by the presentation of a film 'Principles underlying malaria control in India' taken by the Scientific Department, 'Bayer', in co-operation with a number of scientific institutes, giving a bird's-eye view of almost all measures at present adopted for combating malaria.

The lectures on the first day in the afternoon were preceded by an address of welcome by Dr. A. G. Brocke,

the Calcutta Manager and Scientific Adviser to Bayer's, in which he thanked those who had contributed towards bringing into existence the malaria control exhibition. He concluded his address by saying:—

'I would like to express here that the Bayer laboratories in realization of the complicated problem which malaria presents are only too willing to give their whole-hearted co-operation to any malaria control scheme which combines all methods adapted to the local conditions. To demonstrate this intention of Bayer's co-operation is one of the reasons which have prompted us to organize this malaria control conference under the advice of those scientists who are going to speak in these days. I may conclude in stating that we, of the Bayer's pharmaceutical department, including the directors and the investigators in our laboratories at home and those who are working out here as liaison officers, have only one feeling, that is, that we

is much less toxic. Colonel Chopra concluded that, although atabrin is of great importance in private practice, for the time being quinine still holds its place on account of its cheap price and that therefore the cinchona plantations in India should not be abolished until synthetic drugs like atabrin can be supplied at a price allowing their use on a large scale.

Thereafter, Dr. K. V. Krishnan, the professor of malariology and rural hygiene of the Institute of Hygiene, spoke on 'The rôle of the synthetic drugs in the prophylaxis of malaria'. He gave an account of the action of atabrin and plasmochin and explained how their action could be made best use of in field measures. He concluded, after discussing the evidence so far obtained all over the world, both in the laboratory and in the field, that 'plasmochin and atabrin are drugs indispensable and invaluable in the prophylaxis of malaria'.

Another view of the exhibition.

are not the representatives of an industrial organization concerned with the profitable sale of our products but that we have the same mission as any other research institute to contribute to the progress of medical science and thus to the welfare of mankind.'

Thereafter the chair was offered to Colonel Chopra who presided over the rest of the function, opening it with a lecture on 'Present position of anti-malarial drug therapy'. Discussing the anti-malarial drugs in general he said that of the four main crystalline alkaloids of the cinchona bark, quinine is still a very important factor in the treatment of malaria. Some proprietary remedies which he had tested were found to contain cinchona derivatives and did not offer any practical advantage over quinine.

Referring to the synthetic drugs he said that atabrin has an advantage over quinine in many respects, and that it was being used regularly in the Carmichael Hospital for Tropical Diseases with satisfactory results. He added that in all the years they have used it no by-effects of any kind had been noted. He also referred to Cilional, a new preparation of Bayer's, which he said has the same effect on gametocytes as plasmochin but

Finally, Dr. Hora, the assistant superintendent of the Zoological Survey of India, spoke on the 'Larvicidal fishes in India in malaria control'. He enumerated the great variety of larvicidal fishes in India and stipulated that out of these species as a class the ones of the smaller size should be selected. They must be hardy so that they can bear the vicissitudes of the Indian weather, and should be able to breed in confined waters. They should be top-feeders and carnivorous, and finally they must be of absolutely insignificant importance as food.

On the second day the exhibition was open again and at 12 noon another film on malaria taken by the Winthrop Chemical Co., Inc., New York, in co-operation with the State Board of Health, Georgia, was shown.

In the afternoon the chair was taken by Lieut.-Col. A. C. Chatterjee, the Director of Public Health, Bengal, who spoke first on the 'Economic aspects of malaria in rural life of Bengal'. He estimated that on an average 30 to 40 million cases of malaria occur in Bengal every year, a vast majority of them in the rural areas, and the economic loss which the labourers suffer

is not less than 2,25,00,000 rupees in wages alone, to which must be added the cost of treatment incurred. Lieut.-Col. Chatterjee strongly appealed for a co-ordination of efforts for a better control of malarin.

Referring to the synthetic drugs, atebirin and plasmo-chin, he stated that atebirin is at present suitable for private practice only, on account of its high price. For large scale measures however they had still to resort to the cheapest quinine preparations such as cinchona febrifuge in order to provide relief for a maximum number of people with the limited amount of funds that were available for the purpose. He stressed however that the addition of small doses of plasmochin to every quinine treatment was of eminent importance from a public health point of view and that such a 'combination of quinine and plasmochin has given so far the best possible result'. The dose recommended for the purpose is 6 tablets of 0.01 gm. plasmochin which have to be taken distributed over three days. This dose is quite sufficient to destroy the gametocytes present or at least render them non-viable, thus eliminating the source of infection for the mosquitoes. Besides, the total dose in this case was only 1 grain of plasmochin which when issued along with the usual quinine would not produce any severe by-effects, even if the illiterate villager swallowed the whole dose at a time instead of 2 tablets daily.

As far as Bengal is concerned, Lieut.-Col. Chatterjee dealt with the measures of control for combating malaria under seven main headings:—

- (1) Stopping of further creation of well-known sources of breeding grounds.
- (2) Repairing the damage already done.
- (3) Diminution of human reservoir.
- (4) Adopting a systematic and bolder policy of integral land reclamation or, in other words, bonification.
- (5) Giving greater impetus to anti-malaria works by local bodies.
- (6) Appointment of a Government fishery officer.
- (7) Legislation.

and he specially urged the adopting of comprehensive measures on a permanent basis, including anti-malarial engineering measures, natural methods like pisciculture, etc. Nevertheless for giving temporary relief and reducing the mortality, especially in newly-affected areas, drugs have a definite value.

Then Dr. Napier, the professor of tropical medicine of the School of Tropical Medicine, spoke. He dealt with clinical experiences with atebirin and plasmochin from five different points of view, i.e. (1) true causal prophylaxis, (2) clinical prophylaxis, (3) the treatment of the clinical attack, (4) treatment to prevent or reduce the chances of relapse, and (5) gametocyte destruction in the cause of general prophylaxis. He said that no drug will effect (1), (2) can be brought about by the administration of 6 grains of quinine or 0.1 g. of atebirin daily, (3) by 0.1 gm. of atebirin daily for 5 days, or by grains x of quinine twice or thrice daily, (4) by a repetition of the course of atebirin after an interval of ten days and in the case of benign tertian infections by atebirin and plasmochin or of quinine and plasmochin and (5) by 1/6th grain of plasmochin twice daily for three days.

Dr. Napier also discussed in detail the by-effects of atebirin under the following headings: (i) the by-effects wrongly interpreted and wrongly attributed to atebirin (e.g., jaundice which is really discoloration of the skin and sclerotics by the dye), (ii) by-effects that may possibly be attributed to atebirin, and are probably due to individual susceptibility, (iii) by-effects that undoubtedly are caused by atebirin; these are practically all mild but the physician should be ready for their appearance, and (iv) the possible enhancement of these by-effects by the combination of atebirin with plasmo-chin.

The third lecture was delivered by Mr. R. Senior White, the malariologist of the Bengal Nagpur Railway, on 'Species control in malaria' in which he dealt with engineering operations in malaria control. The physico-chemical factors underlying the breeding place preferences of various species have been investigated but

very incomplete results have emerged to date. They seem to be related to the bacterial nitrogen-cycle in the soil underlying the water. Equally the meteorological factors favouring the development of the plasmodia to the sporozoite stage in the mosquito are incompletely understood. The 'malaria season' of a locality is now seen to be the resultant of the interplay of the biochemical factors favouring breeding of the larvae of vector species with the meteorological factors favouring longevity in the adult. It is no longer, therefore, good malariology to use blanket methods against anophelids either in regard to species or to time. For incrimination of vectors extended local dissection is required. For further economy as regards the seasonal factor regular specific larval identifications ahead of the treatment rounds are necessary. The cost of the microscopes involved is amply covered in the first year by economy in larvicides.

The exhibition, film shows and lectures drew large numbers of visitors from the medical profession. The importance of such functions is obvious and the initiative taken by Bayer's in this respect therefore deserves appreciation. It is to be hoped that similar symposiums will be held again.

THE EXCISE CONFERENCE AT NEW DELHI

The excise conference of provincial governments and the native states convened by the Government of India was held at New Delhi on the 8th November, 1937, to consider a number of questions on the excise policy relating to the spirituous preparations. This conference has just concluded its sittings. A number of important subjects of vital interest to the drug manufacturing trade and industry in India were discussed. The following are some of the chief items which were put up for consideration:—

1. Uniformity in rate of duty on spirituous medicinal and toilet preparations and on rectified spirit in all provinces and participating states.
2. Uniformity in rules for the import, export, etc., of spirituous medicinal and toilet preparations and Indian-made foreign liquor and uniform procedure for adjustment of duty thereon.
3. Adoption of a uniform normal spirit strength for all B. P. and other pharmaceutical spirituous medicinal preparations.
4. Unrestricted import and export of duty paid spirituous medicinal preparations (containing less than 20 per cent spirit).
5. Uniformity in procedure for testing samples.
6. Uniformity of rules framed by provincial governments under section 8(2) of the Dangerous Drugs Act, 1930, and uniformity of system of inter-provincial import and export passes in respect of intoxicants.
7. Uniformity of procedure for the denaturation of spirit throughout British India and arrangements of closer liaison between the customs and excise for control of imported spirits and spirituous preparations.

The conference owes its origin to the frequent representations made to the Government by various pharmaceutical concerns in the country to bring about a uniformity in the excise policy all over India. The biggest hindrance on the free movement of spirituous preparations from one province to another at present is the diversity of excise regulations in different provinces. Thus, for example, when spirituous preparations are exported from Bengal to Bombay, the authorities of the latter province refuse to accept the certificate of duty passed by the excise officers of Bengal and insist upon the goods being submitted for re-analysis for spirit content and re-valuation of duty by their own officers before they are delivered to the consignee. In the inland towns of the Madras Presidency, the druggists are not allowed to import spirituous preparations from another province in India, unless they obtain an import permit from the excise commissioner, assess the duty payable on the goods and pay the same in advance. The position has been further complicated during the last two to three years. Prior to 1934, there was a uniform duty of Rs. 5 per proof

gallon in all the provinces on all spirituous preparations. Since then Bombay and Madras have raised the duty to Rs. 10 and Rs. 17-8 per proof gallon respectively for all imported spirituous preparations whereas the duty on local manufactures remained at Rs. 5 per proof gallon. Such regulations naturally hamper the inter-provincial trade in spirituous preparations considerably and further act as a potent incentive to smuggling.

In the interest of the pharmaceutical industry in India it is desirable that inter-provincial and inter-state

barriers should be removed by the introduction of a uniform method of excise control all over India. There are a number of technical difficulties to be considered but it is hoped that the conference will succeed in evolving a simplified procedure which will facilitate a free and healthy trade in spirituous medicinal preparations. Such a step will indirectly have an effect on the price of spirituous medicinal preparations which form quite a large part of the everyday prescriptions of medical practitioners.

Current Topics

Treatment of Malaria with Sulphonamide Compounds

(From the *Public Health Reports, U. S. Treasury Dept.*, Vol. LII, 15th October, 1937, p. 1460)

THE following is believed to be the first report on the use of sulphonamide compounds in the treatment of malaria. It is the translation of a report, by Dr. Amonario Díaz de León, of Cardenas, San Luis Potosi, Mexico, furnished by the Pan American Sanitary Bureau, and is to be published in an early issue of the *Boletin*, issued by that Bureau. This report is published here with the hope that a cautious use of the drug by others may determine whether or not it has real value in the treatment of malaria. As a matter of precaution, mention is made here that reports of idiosyncrasies to this drug are appearing in the literature and that it may not be free from toxic effects. The report follows:

FIRST CASES OF MALARIA TREATED WITH RUBIAZOL ROUSSEL *

In view of the discovery of plasmochin and atebirin after experiments with various colorants, and of the bacterial properties of such dyes as Rubiazol Roussel in streptococic, staphylococic, and gonococic infections, Dr. Díaz de León decided to try it in the treatment of malaria, with such completely satisfactory results in his 15 cases of benign tertian malaria that he believes its antimalarial properties worth further investigation.

Dr. Díaz de León recalls that the treatment of malaria should be adapted to each individual case, after due consideration of the species of the parasite (*vivax*, *falciparum*, *malariae*), its forms (schizont, gamete), the duration of the illness, and the therapeutic properties of the specific drugs—quinine and atebirin (schizontocidal) and plasmochin (gametocidal). The new anti-malarial remedy would probably be classed with the former, since it was tried only in the benign tertian form. Dr. Díaz de León describes the first 4 cases of the 15 which he treated as follows:—

The first patient clearly suffered from benign tertian fever, as he underwent three fever attacks and the microscope revealed *P. vivax*. He was given several tablets of Rubiazol, with instructions to take six per day, two after each meal. Five days later he returned for consultation, feeling perfectly well, and having suffered no attacks during that period. He was advised to continue taking Rubiazol, one tablet after each meal, until one bottle had been used, and to report the results, which were excellent.

The second and third cases were in two brothers who had travelled together through a malarial region, and who suffered the first attack of fever on the same day. Before the treatment, an examination revealed *P. vivax* in the blood of both patients. Rubiazol tablets, two after each meal, were prescribed, for 4 days, then one tablet after each meal until the contents of one bottle had been taken. These two patients suffered only the

initial attack, before treatment, and became perfectly well. Seven days after the first consultation an examination of the blood was made and no parasite was found.

The fourth case was in a woman coming from a malarial region. She had had an abortion, and 4 days later had suffered from general malaise, lack of appetite, and headache. Three days following these disturbances she felt an intense chill, followed by a very high temperature, ending in copious sweat. This cycle of chill, high fever, and sweat was repeated every third day for six times, the last being one day before she came for examination. Though her diagnosis of 'calentura' was corroborated by the symptoms, I proceeded to make a blood smear, staining it with Tribondeau's formula as I had done in the other cases studied, and found unmistakable, abundant parasites of benign tertian. I immediately prescribed Rubiazol tablets according to the system followed in the other cases. On the day following the consultation, when the patient had begun treatment, the last attack appeared (on the day it was due), but lightly, since the chill was slight, the temperature rose only to 38°C., and disappeared in 3 hours, in contrast to the former attacks which lasted 8 or 10 hours. Because of this attack, on the morning following I gave an intramuscular injection of Rubiazol, without stopping the tablets. The attacks did not return and 7 days after the beginning of treatment the patient returned home decidedly improved and taking only three tablets per day. On the twentieth day I had the opportunity of seeing her completely well. This case was the only one in which a second attack occurred, and even in that attack the effect of the Rubiazol was seen. It was also the only case in which I used this drug by injection.

After having treated 15 cases of benign tertian fever with complete success, I am sure that Rubiazol is an effective, specific drug for this form of malaria. I am waiting to experiment with it in other forms later on, since this year the late arrival of the rains has somewhat modified the incidence of malaria in nearby endemic regions.

Induced Epileptiform Attacks as a Treatment of Schizophrenia

By L. A. FINIEFS, M.D. (Paris), M.R.C.S. (Eng.)

(From the *Lancet*, Vol. II, 17th July, 1937, p. 131)

PSYCHIATRISTS have long recognized that in certain mental disorders improvement sometimes follows 'shocks'. In 1929 Nyiró and Jablonsky, reviewing the reports of the Budapest-Lipótmézo Mental Hospital, observed that in a number of schizophrenics remissions had followed attacks of epilepsy. In 1930 Müller reported two cases of catatonic schizophrenia which recovered after having epileptiform fits. These observations and the results of his own experiments promoted von Meduna to evolve a form of treatment by inducing fits artificially.

He first tried intramuscular injections of camphor in oil but these had to be discontinued because of the large dose required. Eventually, pentamethylen-tetrazol, known as Cardiazol (Knoll), proved to be more

*Rubiazol is the French name of one of the sulphonamide preparations.

practical and effective. He has since treated a large number of recent as well as chronic cases of all forms of schizophrenia, irrespective of antecedents, with very good results. No fatality, complications, or late sequelæ were observed. His conclusions are that the best results are obtained in early cases with 6 to 12 months of psychosis and in those that responded with strong fits to the minimum dose of cardiazol. A thorough physical examination is essential before treatment: it must include complete examination of urine, and estimates of blood sedimentation rate, blood urea, blood sugar, and blood pressure. All febrile conditions and pulmonary, cardiovascular, and renal diseases are absolute contra-indications.

The technique is simple. All previous medication, especially of sedatives, should be discontinued for a few days beforehand. Cardiazol is supplied in ampoules of 1.1 c.cm. solution, each containing 0.1 g. of cardiazol in 1 c.cm. It is injected intravenously once or twice a week, with at least two clear days between each injection. The patient, having had an enema the previous evening and no morning meal, is kept in bed and injected at 8 a.m. The initial dose should be 0.5 g. of cardiazol and if this dose does not produce a fit, it should be increased at the following injection by 0.1 g. until the fit-producing dose is reached. This is then repeated at subsequent injections. The highest dose reported is 1 g. The fit occurs $\frac{1}{2}$ to 1 minute after the injection, lasts for about 2 minutes, and has all the dramatic appearance of a grand mal attack. At the onset of the fit, the tongue should be protected by placing a wooden wedge between the jaws. The patient remains dazed afterwards for a short time and restlessness may follow, but this is temporary and should not be controlled by sedatives. More often the patient falls asleep, and he should remain in bed for the rest of the day. Food should not be given for 4 to 5 hours after the fit because there may be vomiting. No other complications have been met with. The number of fits required varies considerably, the average however being 30. Remissions have been obtained with as few as 4 but in general if no mental change is noticed after 20 fits the treatment is stopped.

Epileptiform fits occur in hypoglycæmic coma during treatment with high doses of insulin, and although dangerous to life because of the status epilepticus that may set in, they are generally believed to have a beneficial effect on the mental condition. James, Freudenberg, and Cannon report that they have induced occasional epileptiform fits by injecting cardiazol into some of their patients undergoing high-dosage insulin treatment, on days when insulin is omitted; for the cardiazol fits are less dangerous than those of hypoglycæmia and may be used as a supplement.

Induced epileptiform fits, either alone or in combination with insulin coma, have been used at the Three Counties Hospital for several months with fairly good results. Although no imposing figures of recoveries can yet be produced and the treatment is very active and somewhat rough, no ill effects have been observed in carefully selected healthy young patients. The method appears especially beneficial in early psychosis especially the stuporose and catatonic.

Pneumolysis Combined with Extrapleural Pneumothorax and Oleothorax

By B. RHODES, M.B. (Glasg.)

(From the *Lancet*, Vol. II, 14th August, 1937, p. 377)

THIS paper has been written to describe a method of treatment of pulmonary tuberculosis which has been revived in recent years in Germany and which is arousing considerable interest on the Continent.

Since the value of artificial pneumothorax has been recognized, workers have tried to find means of collapsing the lung in cases where intrapleural adhesions

prevent satisfactory collapse. This problem has stimulated the development of euteration of adhesions and such operations as phrenic nerve paralysis, pneumolysis, and thoracoplasty.

Recently I had the opportunity of visiting Graf's clinic at Coswig, near Dresden, where the method of pneumolysis combined with extrapleural pneumothorax and oleothorax has been in use for three years. I also visited the tuberculosis hospital in Heidelberg where Schmidt has treated the largest number of cases. The value of the treatment in their hands is undoubted.

HISTORICAL

Pneumolysis combined with wax plugging has enjoyed a certain degree of popularity, chiefly on the Continent, since Baer introduced it in 1913. The quantity of wax which can be used is of necessity limited and the degree of collapse is not great. That this operation has not been used more widely is due to the fact that after a time the wax often begins to extrude itself. Other substances have been employed such as rubber, oil, pieces of rib, sponges, and adipose tissue, but their use has been short-lived. In view of its success intrapleurally, air was suggested and employed as a filling medium by Tuffier at the end of the last century. Any successes reported, however, appear to have been largely fortuitous. Great difficulty was experienced in preventing the air from escaping, thereby causing subcutaneous or mediastinal emphysema, and in preventing adhesion-formation with subsequent obliteration of the cavity. In 1932 Sebestyén reported a method of combining extrapleural pneumolysis with intrapleural pneumothorax, which resembles the method to be described in many respects. Zorini, with his 'apicolysse semplice', and Michelsson contented themselves with performing pneumolysis over the diseased area of lung without taking measures to maintain the collapse. As a method of treatment, therefore, extrapleural pneumothorax did not attract much attention until 1934, when Graf began to develop the method which is now in use on the Continent.

THE METHOD

It is probable that most of the pneumolysis which had been carried out in the past were extrafascial. Graf succeeded in freeing the lung from the chest wall in the layer between the parietal pleura and the endothoracic fascia and in filling the resulting space with air. His early results were so encouraging that he has continued with this method and has operated on more than a hundred patients in the last three years. Schmidt, impressed by Graf's work, has operated on a more extensive series of cases in the last two years, and has modified Graf's technique in some important details. Both Graf and Schmidt stress the importance of freeing the lung in the sub-fascial layer, as the cavity thus formed is lined with firm cellular tissue and hæmorrhage does not readily occur. In this layer it is usually possible to free the lung all round, including the mediastinal surface as far as the root, and indeed Graf has succeeded in performing a complete extrapleural pneumolysis. The walls of this space are sufficiently firm and elastic to allow of the maintenance of an artificial pneumothorax without using positive pressures. Should the space become smaller in spite of refills and threaten the re-expansion of the collapsed area before the end of two or three years, there still remains the possibility of maintaining the collapse with oil.

OPERATIVE TECHNIQUE

For details of the operation reference should be made to an article by Adelberger. Here I shall merely summarize the method at present used by Graf and Schmidt. They prefer local anaesthesia with 0.5 per cent novocain. The sitting position for the patient is used, support being provided by a special bolster and pillows. Through a paravertebral incision a piece of the third rib 5 to 6 cm. in length is resected. The intercostal nerve is cut. The correct layer is found by locating the

parietal pleura and working first with the finger and then with a swab on a holder in the fascial plane, which separates easily with a characteristic crackling sound. Care must be taken to carry out the pneumolysis very gently and to avoid pulling any adhesions which may be attached to the ribs. The whole procedure is performed under direct vision, and to make this possible a special lamp which can be placed inside the wound is indispensable. The lung should be freed as far down as seems necessary, allowing ample margin for the inevitable shrinking in the size of the pneumolysis cavity. The mediastinal surface especially should be freed as far as the lung root if this is possible. If the pneumolysis can be carried out entirely subfascially, appreciable hæmorrhage will not occur. Occasionally slight bleeding is seen when the pleura is adherent to a rib. If there is bleeding of any severity it can be controlled without undue difficulty, as the whole operation is performed under direct vision. As the freeing of the lung takes a considerable time to complete, it is advisable to cover the lung, where already separated, with gauze swabs to prevent excessive cooling, and to control the mediastinum should the patient cough during the operation. When the lung has been separated to the desired extent there is a cavity occupying up to half of the hemithorax. The wound is closed by stitching the intercostal muscles as firmly as possible to prevent leakage of air. The subcutaneous tissue and skin are stitched in the usual manner. Graf leaves a small rubber de Pezzer catheter in the wound, attached to an apparatus for maintaining a constant zero pressure in the cavity, for 24 to 36 hours. Schmidt, on the other hand, closes the wound primarily, for he fears infection of the cavity.

AFTER-CARE

The patient is radiographed immediately after the operation and the degree of collapse is clearly seen. At the beginning screening control is carried out daily to determine the frequency of refills. Soon after the operation a fluid level can be made out in the cavity. This consists of blood and serum, and as a rule gives rise to very little trouble. Occasionally the fluid has to be aspirated but it seldom returns. The technique of refills is exactly the same as with intrapleural pneumothorax, but a longer needle is usually required. Refills should be carried out through the space left after resection of the rib, for this area is anæsthetic. The swing of the manometer is considerably less than with intrapleural pneumothorax, and smaller quantities of air are sufficient to maintain the collapse; seldom more than 200 c.cm. are required. In a number of patients the pneumothorax can be maintained as if it were intrapleural. In some patients, however, the lung tends to re-expand in spite of refills. A condition then occurs comparable to obliterative pleurisy. In these cases both Schmidt and Graf fill the cavity with oil. They use Jodipin 20 per cent, but an oil containing bromine is at present being experimented with. The technique of filling the cavity with oil is the same as that of intrapleural oleothorax. The oil is best given at least a week after the initial operation, for then the walls of the cavity are firm and the possibility of rupture into the lung is minimized.

COMPLICATIONS

Complications during the operation are for the most part not serious. Immediate hæmorrhage can usually be controlled by means of electro-coagulation, since the whole proceeding is carried out under direct vision, as mentioned above. Small tears of the pleura have occurred, but have not caused any subsequent trouble. No cases of air embolism have been encountered. After the operation, subcutaneous emphysema is often met with, but it has never exceeded that normally met with after thoracoscopy. Neither Graf nor Schmidt has seen mediastinal emphysema. Delayed hæmorrhage has taken place but has been controlled in each case by aspiration. Infection of the cavity is very rarely encountered, but it is a possibility and is certainly more liable to occur when drainage is used. Schmidt has had no cases of infection since he began to close the wounds

primarily. In the cases of extrapleural oleothorax, perforation of the oil internally or externally is rare, presumably because the walls of the cavity have been allowed to stiffen up sufficiently before the oil is introduced. Spontaneous pneumothorax has occurred in one case of Schmidt's.

INDICATIONS

The indications are the same as for an intrapleural pneumothorax; that is to say, relatively fresh infiltration with cavitation and early infiltration which is tending to spread but cannot be controlled by intrapleural pneumothorax because of adhesions. Sanatorium treatment with adequate rest should of course be tried first, and the intervention should only be carried out if the disease still shows signs of activity. Owing to its selectivity, almost no normal lung tissue is put out of action as almost always happens with intrapleural pneumothorax; therefore it is of use in patients with poor air reserve or in cases with bilateral apical lesions. It may be substituted for an intrapleural pneumothorax when the collapse obtained from this is non-selective owing to adhesions too extensive to be cauterized. An intrapleural pneumothorax which is controlling disease of the middle or lower lobes, although not exerting any influence on the upper lobe, may be combined with extrapleural pneumothorax to make the collapse effective.

Cases with large apical cavities and old stiff-walled cavities with much fibrosis and displacement of the mediastinum are unsuitable for this treatment, for they require permanent collapse measures. If for some reason the immediate condition of the patient is bad, pneumolysis might occasionally be considered as a preliminary to thoracoplasty. Both Graf and Schmidt consider that thoracoplasty is rendered easier after pneumolysis. In cases of long-standing apical disease it may be impossible to carry out pneumolysis because of adhesions which have formed between the pleura and the surrounding tissue. Partial thoracoplasty would then have to be considered.

RESULTS AND CONCLUSIONS

In three years since this operation was started, over 300 patients have been operated on. Complete statistics are not yet available. In November 1936 Schmidt reported three fatal cases out of approximately 100 operated on. Graf early in 1937 reported seven deaths in 107 cases; all seven occurred in the first 40 cases, and in the last 67 there has been no mortality. In no instance could death be ascribed to the operation itself.

It will be evident that sufficient time has not elapsed for the late results of the operation to be assessed. The ultimate fate of the patients in whom an extrapleural pneumothorax has been induced will be watched with interest, for on this will depend the future of the operation. There is undeniably need for a method of treatment less drastic than thoracoplasty for many cases in which artificial pneumothorax is indicated but cannot be carried out. Extrapleural pneumothorax has been evolved in the hope that it will help to meet this need. Graf's and Schmidt's experience seem to justify its wider trial.

Reviews

PROGNOSIS. VOLUME II. 1937.—Published by The Lancet Limited, 7, Adam Street, Adelphi, London. Pp. xx plus 410. Obtainable from Messrs. Butterworth and Company (India), Limited (Publishers), Calcutta. Price, Rs. 7-14.

Prognosis is undoubtedly a neglected subject. It is wrong to say that when the practitioner is faced with the problem of giving a prognosis he has nowhere to turn to find the information he requires. All good textbooks of medicine give a short section on prognosis and there is at least one very valuable 'dictionary' of

prognosis. Nevertheless, there was room for the series of excellent articles on prognosis published in the *Lancet* during the last few years and the publication of the second series in book form will be a matter of considerable satisfaction to many practitioners.

The standard of the articles in this volume is quite up to that of the first series, and the subjects with which they deal appear to be equally important. Not many tropical diseases are dealt with but those that have been selected for inclusion have been fortunate in their exponents: Dr. Ernest Muir contributes the chapter on leprosy and Dr. Hamilton Fairley that on sprue.

The promising-sounding chapter on prognosis in enlargement of the spleen was a little disappointing to us as the author started by stating that tropical conditions would not be considered, though from other points of view it was excellent. The writer, Professor McNee, who is a world authority on the spleen and its functions, says that in chronic myeloid leukaemia the good, if temporary, results of x-ray treatment are obtained when exposure is directed *to the spleen alone* (his italics); this is in keeping with the reviewer's experience. On the other hand the reviewer cannot agree with the figure 300,000 per c.mm. as the normal level for platelets.

The book will prove a very valuable addition to the practitioner's handy reference library.

MODERN TREATMENT IN GENERAL PRACTICE. VOLUME III.—Edited by C. P. G. Wakeley, D.Sc., F.R.C.S., F.R.S.E. 1937. The Medical Press and Circular (8, Henrietta Street, Covent Garden, W.C.2.), London. Pp. xii plus 436, with 54 figures. Price, 10s. 6d.

THIS is the third volume of that most important series of articles which appeared in the pages of our valuable contemporary *The Medical Press and Circular*. The papers were written for the practitioner and are essentially practical. In some instances the titles suggest a subject which is beyond the scope of the ordinary practitioner, but here the articles are written with the object of telling the practitioner what can be done and helping him to assess the chances of his own patient: examples of this type of article are those on treatment of hare lip and of cancer by radium and x-ray, respectively. The writers are all well-known physicians or surgeons at large hospitals in Great Britain and are for the most part teachers.

The treatment described is usually orthodox in principle though by no means textbook transcript, and, if it is new, it is usually well tried and seldom controversial. The chapter on the histidine treatment of peptic ulcer is possibly an exception to this rule; nevertheless, the writer gives a fair presentation of the ease and the fact that he suggests that if the symptoms do not abate within 14 days then further investigations should be carried out, at least insures that little harm will befall the patients of anyone who follows his recommendations; even if the treatment does them no good, and there are some workers who doubt if its action is anything but psychological.

It is difficult to select any article for special praise as the standard throughout is very high, but Sir Humphrey Rolleston has dealt with the difficult subject of cirrhosis of the liver in a very masterly manner. We note that some subjects have been duplicated; there is, for example, another article in this volume on asthma, a subject that was dealt with by another writer in the second volume of the series.

The three volumes will form a very valuable addition to the general practitioner's library.

PATHOLOGICAL PHYSIOLOGY AND CLINICAL DESCRIPTION OF THE ANÆMIAS.—By W. B. Castle, M.D., S.M. (Hon.), and G. R. Minot, M.D., S.D. (Hon.), F.R.C.P. (Edn.), (Hon.). Edited by H. A. Christian, A.M., M.D., LL.D., Sc.D. (Hon.). Oxford University Press, New York. Pp. ix plus 205. Price, 15s. Obtainable from Oxford University Press, Bombay and Calcutta

MINOT and Castle are two names that stand very near the top of the list of workers who have played outstanding parts in the very important advances that have taken place in the study of blood diseases during the last few years. It was a matter of great importance that their collected views on the subject of the anæmias should be made available to a wider medical public than they would be if they remained only as a section of a medical encyclopædia that has not a very wide circulation outside the United States of America. We therefore welcome the publication as a separate volume, by the Oxford University Press, of this important contribution to medicine.

The early sections of the book make very attractive reading and their interpretation of the physiology of the erythron is clear and convincing. The section dealing with diagnostic methods is concise and useful, but not of course exhaustive.

The classification that they have suggested is in keeping with the modern tendency. They have however only adapted two major groups, the first being 'anæmia due to blood loss or increased blood destruction'; the two causes here seem to be so essentially different that most hæmatologists have separated them, but the authors justify this classification on the grounds that in both cases there is physiologically hyperactivity of the bone marrow, whereas in all other anæmias there is hypoactivity; this claim also seems to call for explanation, though it may be true from some points of view.

The descriptions of the various types of anæmia, in which the authors naturally follow their own classification, are in some ways disappointing, as they do not seem to be complete, either from the clinical or from the hæmatological point of view. There is seldom any clear-cut blood picture given and, whilst it is true that the blood picture is liable to variations in most conditions, a little judicious dogmatism would have been welcomed by the class of reader for which the book was originally designed. There are also a number of loose statements, such as 'tetanic symptoms, probably due to loss of calcium in the stools'. It is not at all clear how their pernicious anæmia of pregnancy differs from Wills' anæmia, or even if they themselves consider it different.

There is an invaluable bibliography consisting of 646 references with the title of the paper given in each instance; this makes a bibliography so much more useful and only in the interest of space, which however is often a primary consideration in a medical journal, should they be omitted.

In conclusion, it may be said that the book is a most important contribution to hæmatology and will prove invaluable to the specialist and research worker. We do not however think that it is the ideal book for the student or practitioner, and we consider the subject-matter much more suited to its present form as a separate book than to a section in an encyclopædia of medicine.

WHEELER AND JACK'S HANDBOOK OF MEDICINE.—Revised by John Anderson, M.D., F.R.F.P.S. (Glas.). Tenth Edition. 1937. E. and S. Livingstone, Edinburgh. Pp. xvi plus 703. Illustrated. Obtainable from Messrs. Butterworth and Company (India), Limited (Publishers), Calcutta. Price, Rs. 8-8

'WHEELER AND JACK' has been in existence for forty-three years and is too well known to require any introduction. The present edition, revised by John Henderson, has undergone a number of alterations, modifications, and additions, which have been necessitated by advances in knowledge. In order to keep the

size of this volume within limits, certain parts, *viz*, the section on immunity, have been omitted.

The arrangement follows more-or-less orthodox lines and practically the whole range of general medicine is included. The various diseases are dealt with concisely, and the book provides a good summary of medical knowledge and practice.

A few sections are insufficiently detailed, for instance, hepatic puncture has been regarded as practically the only method of diagnosis in kala-azar, and information about the use of synthetic drugs in malaria is too meagre. Despite the advances in our knowledge of anæmia, the old classification of primary and secondary forms has been still mentioned. The Mantoux test has not been mentioned in the diagnosis of tuberculosis.

Otherwise, the book is a valuable one and has an impersonal quality. Students, especially in the medical schools of India, can safely turn to it as a reliable and lucid guide.

R. C.

RECENT ADVANCES IN THE STUDY OF RHEUMATISM.—By Frederic John Poynton, M.D., F.R.C.P. (Lond.), and Bernard Schlesinger, M.A., M.D. (Camb.), F.R.C.P. (Lond.). Second Edition. 1937. J. and A. Churchill, Limited, London. Pp. x plus 380, with 51 illustrations. Price, 15s.

THE subject of rheumatism in its varied aspects has resulted in the development of such a vast literature that it is difficult to keep pace with it. The appearance of the second edition of this book in the *Recent Advances* series is therefore welcome. The volume affords an excellent review of all recent publications with adequate discussions and comments.

After an introductory note on nomenclature, the authors have adopted a classification dividing rheumatic diseases, as simply as possible, into acute rheumatism, particularly that affecting children, and into chronic rheumatism which has been subdivided into rheumatoid arthritis and osteo-arthritis.

Recent investigations do not seem to promise the discovery of any one outstanding predisposing cause, but rather a combination of many which tend to lower the general health. Most authorities favour the view that damp is a decided factor in rheumatism, although the evidence collected by the Medical Research Council Committee throwing doubt upon this idea cannot be overlooked.

Elaborate histological examination of the pathological lesions in the acute condition has now shown that the Aschoff node, regarded almost universally as the hallmark of the disease, is in reality only a stage in the pathological process. It is not the essential lesion in the myocardium; rheumatic infection has direct toxic action on the cardiac muscle fibres. The widespread distribution of inflammatory rheumatic foci throughout the vascular system is now generally recognized. No striking new discovery has been made concerning rheumatic nodules and the reason for their presence in some cases and their absence in others is still a mystery. The bacteriology of acute rheumatism still remains a controversial problem. A chapter is allotted to electrocardiography describing how early suspected lesions can be confirmed. Preventive, immediate and convalescent treatment have been clearly described and the importance of prolonged rest is stressed. The chapter on acute rheumatism in childhood has been brought up to date and a new one written, devoted to the industrial aspect of rheumatism which is becoming of increasing importance. There is no reference of sympathectomy for the relief of pain in certain cases of rheumatoid arthritis, possibly because the operations of this type do not affect the underlying disease process.

The number of illustrations has been increased; some of these are of outstanding interest. There are references to the literature at the end of each chapter. The get-up of the volume is excellent as would be expected of Messrs. J. and A. Churchill. The book should be in the possession of practitioners and senior medical students.

R. C.

ELECTROCARDIOGRAPHY.—By C. C. Maher, B.S., M.D. Second Edition. 1937. Baillière, Tindall and Cox, London. Pp. xvi plus 254. Illustrated. Price, 18s.

CRITICISM has often been made that our practice of medicine is becoming too mechanized. If the machine serves as a corroborator of clinical observations, and not as the sole means of making the diagnosis, the criticism is not justified. This conclusion applies to electrocardiography that has now been established as a standard part of cardiovascular diagnosis. The publication of another edition of Dr. Maher's treatise within two years shows its popularity.

The book begins with a brief résumé of the modern clinical concepts of cardiovascular disease, conduction system of the heart, electrocardiograph and the fundamental principles of the electrocardiogram. Next, it deals with the arrhythmias and conduction deformities, which comprise over a hundred pages. This is followed by sections on axis deviation, coronary disease, drug effects, clinical syndromes, and diagnosis. The last chapter gives an outline on the routine interpretation of electrocardiograms.

The book is a practical one with a lucid style and characterized by brevity. Illustrations are profuse and vivid. There are diagrams and anatomical sketches to show the relationship of the electrocardiogram to the Purkinje system. A large number of tracings have been reproduced with regular tabulated interpretations, actually done in the laboratory, so that even a novice can follow them.

It will serve as a very useful reference book for practitioners and students.

R. C.

THORACIC SURGERY: A REVISED AND ABRIDGED EDITION OF SAUERBRUCH'S DIE CHIRURGIE DER BRUSTORGANE.—By F. Sauerbruch and L. O'Shaughnessy, F.R.C.S. 1937. Edward Arnold and Company, London. Pp. viii plus 394. Illustrated. Price, 50s.

THIS book, consisting of 360 pages of text, puts the present position of thoracic surgery very clearly. It is now nearly ten years since Sauerbruch first published his *Die Chirurgie der Brustorgane*, and the advances made in recent years together with the increasing interest in the subject have prompted the authors to present this revised and abridged edition in English. The hope is expressed by the authors that a more general understanding of the principles of this branch of surgery by those indirectly concerned, *viz*, the physician and general surgeon, will benefit many more patients than is at present the case. This is a worthy belief which the book should do much to fulfil. The senior author, Sauerbruch, is one of the pioneers of thoracic surgery, and his immense experience is reflected in the quiet authority with which the book is written.

It is printed on excellent paper and adequately illustrated. The first 32 pages are devoted to chapters concerned with general principles. It then proceeds in orderly sequence to deal with everything affecting the thoracic cage and its contents, ending finally with an appendix on the surgery of cardiac ischæmia. There is at the end of the book a very complete and up-to-date bibliography, and an authors' index. Nothing of importance has been omitted and even the rarest of surgical conditions affecting the thorax receive attention.

The introduction of case histories to illustrate the method adopted in dealing with particular types of case is very effective and greatly enhances the value of the book.

In all operations within the cavity of the chest, general anaesthesia is considered essential because of the danger of reflex disturbances, and of the anaesthetics available either given under positive pressure is considered the method of choice. Gas and oxygen are never employed. It is noted that there is no mention of spinal anaesthesia. For operations on the chest wall, local anaesthesia is preferred, except perhaps in very nervous patients where psychological dangers have to be considered.

In a book otherwise so complete, the reviewer feels that perhaps a little more detail might have been given to the treatment of empyema. For example, the details of intercostal drainage after the manner of Bülau are said to be shown by figure 46, which really only shows a tube draining the chest. In the same paragraph blowing fluid from one Wolff bottle to another is recommended as a method for bringing about expansion of the lung on the affected side. Is this method of much value? Again in the discussion of thoracostomy with rib resection the depth to which the drainage tube should be placed is not given, although it is stated that 'the drain may be shortened as time progresses'. At what intervals of time and by how much? Irrigation also as a method of treatment does not receive much mention.

Sauerbruch prefers two-stage lobectomy, inserting at the first operation a paraffin-wax plombe. We are not told how long after the insertion of the plombe the second stage is carried out. The technique of plombage which finds some favour in the Sauerbruch clinic is otherwise very fully dealt with. Surely the value of postural treatment for lung abscess and bronchiectasis, and especially its use as a preliminary to lobectomy, for the latter condition would justify a more detailed description?

A very full account of diseases of the thoracic oesophagus and their treatment is given but it is observed that Knight's work in connection with the relief of cardiospasm is not mentioned, nor is Grey Turner's operation of excision of the oesophagus for carcinoma.

These are minor criticisms, and there is no doubt that this book is a valuable addition to the literature on the subject of thoracic surgery. It is strongly recommended to all general surgeons and physicians, for the close co-operation of physician and surgeon is nowhere more essential than in diseases affecting the thorax.

F. A. B. S.

ELEMENTS OF SURGICAL DIAGNOSIS.—By Sir Alfred Pearce Gould, K.C.V.O., C.B.E., M.S., F.R.C.S. Eighth Edition, revised by Eric Pearce Gould, M.D., M.Ch. (Oxon.), F.R.C.S. (Eng.). 1937. Cassel and Company, Limited, London. Pp. xv plus 718. Illustrated. Price, 10s. 6d.

THIS little book needs no comment on its usefulness to students entering the surgical wards. The book appeared a little more than fifty years ago and the fact that, notwithstanding many similar publications since it first saw light, it has held its own during the last half century is an ample proof, if any proofs are needed, of its popularity among students and young practitioners.

The present is a revised edition, coming in after a lapse of eight years. An earlier issue of the edition must have been missed by many. Advances in surgical pathology and application of advances in radiology for diagnosis, made during the last decade, necessitated some alterations and readjustments especially in regard to nomenclature to bring the book up to date. We would have, however, been happier to see 'benign giant-cell tumour' used in place of 'osteoclastoma' and should think that the use of 'neuroma fibroma' has remained due to inadvertence.

A wider application of radiology in diagnosis has also been stressed. Many new plates have replaced old ones and in this we agree with the author's remarks that 'the present series will prove easier to interpret'. But for this, the scheme and scope of the book remains the same. There is little doubt that in the present edition will be found the same skilful collections of essential details for diagnosis to enable the present generation of teachers in surgery, of all the English-speaking nations, to recommend the book as a sound and comprehensive compendium, suitable to students and young practitioners; although we are confident that the book will also be read with interest and profitably by a wider and more senior section of medical men and women.

We, however, feel constrained to say that in the matter of printing, in the plates and get-up of the book, we could not find any subject for congratulation.

Indeed, it is disappointing to see that such valuable material should have been so poorly printed. It is surprising that many of the defects were not remedied during the proof reading.

S. C. S.

DEMONSTRATIONS OF PHYSICAL SIGNS IN CLINICAL SURGERY.—By H. Bailey, F.R.C.S. (Eng.). Sixth Edition. Revised. 1937. John Wright and Sons Limited, Bristol. Pp. xii plus 284, with 358 illustrations, some of which are in colour. Price, 21s.

THIS, the sixth edition of a book which first appeared in 1927, has in its present form been fully revised, certain parts of the text having been recast and rearranged so as to render the student's task even easier.

There is otherwise little change from preceding recent editions. The book is well on the way to becoming a hardy annual and this no doubt is a reflection of its great popularity. That its popularity is richly deserved can readily be appreciated, as it is one of the finest books on clinical surgery in the English language. None of the important clinical signs is omitted, it is concise and always to the point.

All medical undergraduates at the commencement of their clinical training are strongly advised to buy and study this book. They can be assured of full value for their money.

F. A. B. S.

CANCER AND DIET: WITH FACTS AND OBSERVATIONS ON RELATED SUBJECTS.—By F. L. Hoffman, LL.D. 1937. The Williams and Wilkins Company, Baltimore. Pp. xx plus 767, with 15 illustrations. Price, \$5.00. Obtainable from Messrs. Baillière, Tindall and Cox, London. Price, 22s. 6d.

DR. F. L. HOFFMAN, the expert in vital statistics, in his campaign against cancer has produced a scientific survey of the subject of cancer and diet. The results have been stated statistically under each food or group of foods through analysis of 2,234 questionnaires obtained by interviews with cancer patients at hospitals in several American cities, and 1,149 questionnaires for non-cancerous controls. The work is divided into four sections the first of which is an extended review of the literature on the subject. The array of opinion presented reveals an amazing amount of contradictory theories and results. Some advocate vegetarian diet, while others emphasize high-protein diet as a preventive and possibly curative measure. Most writers, however, are agreed that excessive nutrition, if not the chief cause, at least is a contributory factor of the first importance. The evidence put forth is contradictory to the recent views of Lochart-Mummery—'Various suggestions have been put forward that the incidence of cancer is related to certain foods, or absence of foods, but there is no evidence whatever to support such an idea, and a very great deal of evidence to refute it'.

The second section is a statement of the essential statistical facts of food consumption and the changes which have occurred during recent times to illustrate the growing tendency toward the use of modified or changed food products in contrast to the more natural foodstuffs of former years. It is held that these changes have introduced many dangerous factors, the nature of which is, as yet, not very clear. The author is, however, convinced that the chief cause of cancer in our modern civilization is the increasing urbanization of the people consuming modified substances, as a rule, in excessive quantities and more or less unnatural conditions of existence.

The third section deals with cancer metabolism as it is affected by various organic and inorganic food compounds. This applies particularly to the question of alkalosis and acidosis, to vitamin deficiency or excess, to mineral salts, to excess of animal proteins and to carbohydrates.

The fourth section represents the more general facts concerning cancer patients and non-cancerous controls secured by the questionnaire method. For instance, it is shown that constipation prevailed more in cancer patients than in controls.

The statistical conclusion reached is that a principal difference between the cancer patients and the controls is the quantitative and qualitative richness of the diets of the former. Although it may not be universally accepted, the accumulation of data in this book is commendable.

R. C.

DISEASES OF THE EYE: A TEXTBOOK FOR STUDENTS AND PRACTITIONERS.—By Eugene Wolff, M.B., B.S. (Lond.), F.R.C.S. (Eng.). 1937. Cassell and Company, Limited, London. Pp. xi plus 234, with 120 text illustrations and 5 coloured plates. Price, 15s.

In the last few years so many small textbooks on diseases of the eye for the use of students and medical men have been published that one wonders at the appearance of yet another. The book consists of 225 pages divided into 24 chapters, 120 figures and 5 coloured plates.

There is nothing new in the subject-matter, but one is impressed by the number of anatomical drawings which very rightly places emphasis on the importance of a sound knowledge of anatomy in the study of ophthalmology. These are excellently produced but are mostly standard ones, although the author has taken credit for their originality in many cases.

The treatment of trachoma and its sequelæ are open to criticism. Few will agree that daily paintings with 2 per cent silver nitrate are necessary when less painful applications are equally efficacious. To the experienced ophthalmologist the only satisfactory treatment for cicatricial entropion is the Webster's mucous-graft operation. Few will agree that an iritis occurs in most cases of cataract extraction and that a general anaesthesia is necessary for the removal of a post-operative iris prolapse. The importance of facial akinesia and its technique have been unfortunately omitted, likewise pre-operative hypnotics. The author will indeed be fortunate if he can get patients to remain in bed for 10 to 12 days after the removal of a cataract and it is hardly necessary to do so after three days.

The book is well written, profusely illustrated, and its teaching orthodox.

We can strongly recommend it as a useful and thoroughly practical book for students and medical men working in India.

E. O'G. K.

THE RÔLE OF CHEMIOTAXIS IN BONE GROWTH.—By A. P. Bertwistle, M.B., Ch.B., F.R.C.S. (Edin.). 1937. Henry Kimpton, London. Pp. xii plus 59, with 32 illustrations. Price, 8s. 6d.

This is a small book but it embodies an interesting and novel idea in connection with bone formation. This subject has been in the past, and still is, a matter for speculation, but the problem remains unsolved all the same. The theory advanced by the author of this volume will therefore be an interesting addition to it.

The object of this book is to describe what the author has chosen to call 'disruptive chemiotaxis', i.e., 'the power of certain substances of attracting and drawing into themselves certain soft, living structures'. With the help of such a process, which however is new to medicine, he wants 'to lay down a law which, based on histological grounds, will be found to cover the whole field of bone pathology, viz., that whenever young fibrous tissue, particularly young blood vessels, come in contact with bone or a calcified deposit, new bone formation occurs'. It must be confessed however that though these terms are quite attractive the perusal of the book does not carry much conviction and it gives one the impression that their introduction to scientific literature is hardly justified.

The book contains some good descriptions of the histology and development of bone and a fairly good account of the relation of the periosteum to bone growth. The chapter dealing with ectopic bone formation may also be read with interest. At the end of each chapter there is a list of references which are fairly comprehensive. The paper, printing and execution of the diagrams are all very good.

It is somewhat difficult to know exactly the aim of the writer in publishing a book of this nature. The descriptions are too short and sketchy in character and in some places not up to date. The use of the words myeloma for giant-celled tumour (osteoclastoma) and endosteal and periosteal sarcoma for osteogenic sarcoma cannot be taken as very modern. But in spite of all these drawbacks the writer is to be congratulated for the ingenuity of his ideas and the book should be read by all who may be interested in the subject of osteology.

M. N. D.

DRUGS AND GALENICALS: THEIR QUANTITATIVE ANALYSIS.—By D. C. Garratt, B.Sc., Ph.D. (Lond.), F.I.C. 1937. Chapman and Hall Limited, London (Henrietta Street, W.C.2). Pp. xiv plus 422. Price, 25s.

As the name indicates, the book deals only with the quantitative analysis of drugs and galenicals. The drugs have been arranged alphabetically and the general scheme adopted is that used in the *British Pharmaceutical Codex*. The principle involved in each method has been shortly explained, and this is followed by a concise but clear description of the experimental details. The reference to the original papers completes the monograph on each substance.

The methods given in *British Pharmacopœia* 1932 have been avoided unless they are of general application. The author has supplemented most of the methods by additional explanatory notes which make them very valuable to workers who have not attained sufficient experience. Alternative methods, depending upon entirely different principles, have been suggested to enable one to check his results wherever possible, and of the published methods only those which showed no inherent weaknesses and were found to be based on sound scientific principles have been included. Separate sections have been allotted to fixed oils and fats and essential oils, and there are some useful appendices.

The wide experience of the author in this branch has thus enabled him to collect a large fund of useful material in a concise volume. The determination of small quantities is claimed to be a new feature in the monographs and the manual should therefore be useful to those engaged in toxicological work. The book should prove extremely valuable not only to analysts engaged in the examination of drugs and galenicals but also to various research workers in the wider field of plant products of scientific and economic importance.

S. G.

CHEMICAL METHODS IN CLINICAL MEDICINE: THEIR APPLICATION AND INTERPRETATION WITH THE TECHNIQUE OF THE SIMPLE TESTS.—By G. A. Harrison, B.A., M.D., B.Ch. (Cantab.), M.R.C.S. (Eng.), L.R.C.P. (Lond.). Second Edition. 1937. J. and A. Churchill, Limited, London. Pp. xi plus 585, with 3 coloured plates and 86 illustrations. Price, 21s.

A QUARTER of a century ago the chemical pathologist was a novelty, even on the staff of a general hospital, and we remember the lifted eyebrows when the predecessor to the author of the book under review was appointed to one of London's largest hospitals. Times have, however, changed and the help of the chemical pathologist, or biochemist as he is now more often called, is more important to most physicians than that of the bacteriologist. Nor do we believe that he has yet reached the peak of his usefulness.

The great advances that have been made during the last seven years have necessitated complete revision and considerable expansion of this book. Amongst the sections that have been revised is that on the van den Bergh test: the old cut-and-dried explanation of the 'direct' and 'indirect' reaction—'non-direct' would be a better term, the author considers—is given, but rather as a matter of history and without any conviction that it is the right one—in fact with a fair degree of certainty that it is not. For practical purposes he considers the 'indirect' test one of considerable value, but the 'direct' one liable to misinterpretation.

The description of gastric analysis is very clear and there are some helpful 'tips' which other books usually omit; there is also a useful table of the gastric findings in different conditions. Uffelmann's test for lactic acid is given. The next paragraph opens with the statement that 'qualitative tests for lactic acid are unsatisfactory'; it seems probable that this is a misprint for 'quantitative'.

Fouchet's test for bilirubin in the urine is given and is illustrated by a coloured plate.

A few important references are given at the end of most of the chapters; this is a point where more completeness would be welcomed by, we believe, most readers.

On the whole it is a very practical and generally useful book which we can strongly recommend to both physicians and biochemists.

L. E. N.

FLUORINE INTOXICATION: A CLINICAL HYGIENIC STUDY WITH A REVIEW OF THE LITERATURE AND SOME EXPERIMENTAL INVESTIGATION.

By Kaj Roholm. 1937. Published by Nyt Nordisk Forlag, Arnold Busck, Copenhagen (Graabrdretorv, 14). Pp. xi plus 364. Illustrated. Obtainable from H. K. Lewis and Company, Limited, London

This volume is a comprehensive review of the whole problem of fluorine in biology with special reference to its importance in industrial poisoning. The symptoms of fluorine poisoning in man and animals and its absorption, excretion and retention in the tissues are fully discussed. Several chapters are devoted to experimental work on rats, pigs, calves and dogs. The morbid anatomy, histology and biochemical changes in fluorine poisoning are well treated and should be of considerable interest both to the pathologist and clinician alike. The pathological changes found in the bones are a case in point. There are a number of first-class illustrations and a comprehensive review. So many organs are affected in this condition that indeed almost any medical man should be able to cull something of interest from its pages.

A TEXTBOOK OF NEURO-ANATOMY.—By Albert Kuntz, Ph.D., M.D. Second Edition. 1937. Baillière, Tindall and Cox, London. Pp. 519. Illustrated with 307 engravings. Price, 27s.

In this second edition of the book, the first of which was published about six years ago, much of the text has been revised and some of its contents have been rewritten. The book has improved in many details of its text and diagrams, most of which are truly illustrative of the context.

In going through this book one is struck with some special quality which is not usually seen in the ordinary textbooks. The scheme of the book is scientific, comprehensive and is indeed well designed and of a high order. Endeavour has been made to work out the details of the complicated anatomy of the human central nervous system on the basis of the simpler fundamentals of the vertebral nervous system and to correlate those details with the basic structural plan—an endeavour wholly scientific.

Notwithstanding the expressed object of the author, to write a book to enable the beginner to grasp the difficult subject easily, we think the presentation has been carried beyond the easy understanding of the under-graduate medical students. The book however is comprehensive and the attempts of the author in dealing with the subject from the standpoint of comparative anatomy, phylogenetic and fundamental structural relationship will be appreciated more by that group of advanced students who are interested in further studies of the central nervous system and its disorders. Every part has been discussed with the microscopic and gross anatomy and also in relation to its functional significance. One will therefore find every aspect of the nervous system which is to be learnt for the investigation of its disorders.

A practical utility of the book will be seen at the end in so far as it has given the practical methods to be applied in the study of the more important parts of the central nervous system. The value of the book has been further enhanced by the introduction of a series of clinical illustrations which will be very profitably read by those who are engaged in the special study of nervous disorders.

We have nothing but praise of the publisher's task which has been done creditably throughout.

M. N. D.

A BRIEF OUTLINE OF MODERN TREATMENT OF FRACTURES.—By H. W. Splers, A.B., M.D. Second Edition. 1937. Baillière, Tindall and Cox, London. Pp. ix plus 137. Illustrated. Price, 9s.

This little book from the pen of the professor of orthopaedic and fracture surgery, College of Medical Evangelists, Los Angeles, California, has deservedly entered its second edition and is likely to continue in demand. Fundamentals are not obscured and accepted practice is clearly stressed. The text is to the point and the illustrations are clear-cut line drawings. There are no useless x-ray reproductions. The senior student who has digested the contents of this short treatise will ensure for himself a sound foundation in this difficult branch of practical surgery. The publishers are to be congratulated on the paper used in this book. The absence of glaze is surprisingly easy on the eyes especially by artificial light.

H. R. R.

ANTENATAL AND POSTNATAL CARE.—By F. J. Browne, M.D. (Aberd.), D.Sc., F.R.C.S. (Edin.), F.C.O.G. Second Edition. 1937. J. and A. Churchill, Limited, London. Pp. xviii plus 588, with 79 illustrations. Price, 18s.

PROFESSOR BROWNE'S 'Antenatal and Postnatal Care' has already become a standard textbook on this subject. The second edition will be welcomed for the addition of much useful material which widens the scope and usefulness of the book.

There is a new chapter on constructive educational and social aspects of antenatal care by Professor Fairburn and another on the subject of radiology in obstetrics by Dr. R. W. A. Salmond. The section on diet in pregnancy has been enlarged and more prominence given to this important subject. The section on postnatal care now includes a description of puerperal exercises but the hygiene of the later puerperium and the care of the lactating woman still receive very little attention.

M. I. N.

MOTHERCRAFT: ANTENATAL AND POSTNATAL.—By Reginald C. Jewesbury, M.A., D.M. (Oxon.), F.R.C.P. (Lond.). Second Edition. 1937. J. and A. Churchill, Limited, London. Pp. ix plus 188, with 21 illustrations, 13 in colour. Price, 10s. 6d.

This excellent book is based on the principles of Sir Truby King's methods of infant feeding. The author states 'I have adhered to these principles because I consider they are founded on sound common sense, that they provide a scientific working guide, and, last but not least, that the results obtained from them are eminently satisfactory as judged from their practical application to a very large number of infants in this country (England). The remarkable work of Truby King in New Zealand is widely known but perhaps the most striking testimony of it is the marked fall in the infantile death rate in the Dominion since he devoted himself to infant welfare'.

While the principles of Sir Truby King's methods have been widely accepted the practical application of them has been necessarily limited to countries where special facilities and more extensive mothercraft teaching are readily available. The present edition has, by recommending whole milk and the introduction of solid food at an earlier age, indicated lines along which the

methods advocated may be more easily adapted to use in a country like India. This book should be widely read in a country faced with the problem of an enormous infantile mortality.

M. I. N.

THE MEDICO-LEGAL POST-MORTEM IN INDIA.— By D. P. Lambert, M.D., Ch.B., D.T.M. & H. (Univ. Edin.). 1937. J. and A. Churchill, Limited, London. Pp. vi plus 113. Price, 5s.

In this little book the author has set forth briefly but lucidly the full technique of a post-mortem examination undertaken for medico-legal purposes in India. He has further attempted to present the distilled essence of descriptions of appearance of deeds of violence and also of the normal seen in a mortuary. Results of characteristic modes of attack, such as a *lathi* blow, are very well described.

Almost every statement is definite. Of controversial matter and unnecessary details there is hardly a trace. Even disparaging remarks on textbooks are very few. Incidentally, the book will not replace textbooks.

The agreeably natural style makes the narrative flow like that of a detective story. 'All parts of the body are open to the murderer. The suicide can only reach a limited area.'

Certain items may be reconsidered in the next edition: under *hanging* the reasoning appears to be involved; under *abortion* and *lead poisoning* not much help will be given by the blue line on the gums, in acute cases; under *infanticide* precipitate labour causing fatal injuries and accidents to the infant may require to be proved or disproved. Perhaps blood from a corpse, dried on filter paper, may be advantageously preserved for a determination of blood group.

Of printer's errors only one attracts attention. On page 47 *hard* lens should be *hand* lens.

The size, the paper, the printing and the binding are good. A lower price would have been more in keeping with the economic conditions of India.

S. D. S. G.

ILLUSTRATIONS OF REGIONAL ANATOMY. SECOND EDITION.—By E. B. Jamieson, M.D. Sections I to VII. Section I: Central Nervous System (containing 48 plates). Section II: Head and Neck (containing 63 plates). Section III: Abdomen (containing 37 plates). Section IV: Pelvis (containing 33 plates). Section V: Thorax (containing 30 plates). Section VI: Upper Limb (containing 42 plates). Section VII: Lower Limb (containing 52 plates). E. and S. Livingstone, Edinburgh. Available from Messrs. Butterworth and Company (India), Limited (Publishers), Calcutta. Section I—Price, Rs. 4-12; Section II—Price, Rs. 8-8; Section III—Price, Rs. 3-12; Section IV—Price, Rs. 2-8; Section V—Price, Rs. 2-12. (The price of the complete set of seven sections—sections 6 and 7 having been published in 1936—is Rs. 31-8.)

It is just a little over two and a half years ago that we reviewed the first edition of this publication (it appeared in October 1934) and we began with the following sentence: 'We do not feel that we are rating these books too high when we say that they are what anatomy students of a number of generations have been waiting for'. This opinion appears to have been justified for the enthusiastic reception of this valuable collection of drawings has led to the rapid exhaustion of the edition so that another one became necessary.

When it was first published this collection of plates was in five parts or sections dealing with the nervous system, the head and neck, the abdomen, the pelvis and the thorax respectively. There was an immediate demand that the collection should be made complete by preparing similar drawings of the limbs with the result that the author produced two more sections in June 1936, one of upper and the other of the lower limb.

The second edition appears to be only composed of the original five parts, presumably the other two parts, appearing a good deal later, are not yet exhausted. We have, however, received all seven parts and as one would expect parts VI and VII are of exactly the same high standard as the other five.

There have been a few changes from the first edition and these are definite improvements. More plates are now coloured, this will lead to more easy identification of different structures and thus save a certain amount of time to the student and also improve the mental picture he will retain of any given diagram.

For the benefit of those who are not familiar with the first edition we will recapitulate some of the points that appeal to us as recommendations.

The loose leaf system allows of the rearrangement of the figures in any way that may be suitable for special circumstances, and it also permits of their separate use in the epidiascope or fixed on the black-board for illustrating lectures. The actual method of filing is original and highly satisfactory as it is secure and is very easily operated.

This collection of plates will be found of great use to students and teachers of anatomy, especially in a country such as India where many of the smaller medical teaching institutions have not recourse to the cadaver or museum specimens for purposes of demonstration. When the excellence of their production is considered this 'picture gallery of anatomical studies' is issued at a very reasonable price, and a student not blessed with unlimited means would do well to deny himself something so as to obtain them.

A TEXTBOOK OF BOTANY FOR MEDICAL, PHARMACEUTICAL AND OTHER STUDENTS.— By Prof. James Small, D.Sc. (Lond.), Ph.C., F.L.S., M.R.I.A., F.R.S.E. Fourth Edition. 1937. J. and A. Churchill, Limited, London. Pp. x plus 717, with over 1,350 illustrations. Price, 21s.

According to the author, the book is designed to replace late Professor Reynold Green's *Manual of Botany* which, though a valuable textbook on the subject, was to some extent out of date. The author has not followed the customary arrangement into morphological and physiological subdivisions. He has dismissed physiological processes and anatomical and morphological features at the point where they become dominant in the life of the plant. There is a difference of opinion on this point as to whether it is an advantage to beginners. The special feature of the book is the incorporation of diagnostic characters of certain medicinal plants in appendix I, which will be very useful to medical and pharmaceutical students. The appendices II and III will serve as a guide to students in their practical work. In the appendix IV, the author has nicely collected together the life-sketches of lower plants.

The book has been copiously illustrated; its language and style are simple and elegant. In the present edition, the author has dealt with recent advances in plant physiology, e.g., hormone (auxine), enzyme chemistry, statoliths theory, etc., in a masterly way. But so far as mitosis is concerned, the statements on pages 33 and 34 are not in line with the recent advances in the branch of cytology (Sharp, Darlington).

The book would have been much more valuable to the Indian students had there been examples from Indian flora in the morphological portion.

S. M.

THE ELEMENTS OF MEDICAL TREATMENT.—By R. Hutchison, M.D., LL.D. (Hon.), D.Sc. (Oxon.), F.R.C.P. Third Edition. 1937. John Wright and Sons, Limited, Bristol. Pp. 194. Price, 5s.

The reviewing of the third edition of this book, which even in its short life has become a classic, gives an excellent opportunity for cynical ruminations on modern medical progress. We will content ourselves with the observation that this book demonstrates how very little the *elements* of medical treatment do change

in a period of five years. People become constipated, have diarrhoea, or bleed, hearts fail, and worms inhabit our intestinal tracts, and we treat them in much the same way as we did five and even ten years ago—perhaps in the last-named instance there are more effective methods of getting rid of them than the author suggests—though if people don't sleep there are perhaps more ways of making them do so nowadays.

This is a book that every medical student should be made to read and digest before he is allowed to qualify, and every practising doctor at intervals of not less than five years, as an antidote to the flood of proprietary medical literature with which he is daily inundated. At twice its price, the book would be a bargain.

L. E. N.

Abstracts from Reports

HEALTH ORGANIZATION OF THE LEAGUE OF NATIONS. ANNUAL REPORT ON THE RESULTS OF RADIOTHERAPY IN CANCER OF THE UTERUS. FIRST VOLUME. EDITED BY J. HEYMAN, STOCKHOLM

The present volume is the first of a series of annual reports on the results of radiotherapy in cancer of the uterus, which the health committee of the League of Nations has decided to issue. The principal object of the reports is to provide a convenient work of reference for those who wish to know, statistically, the results obtained in radiotherapy of the cervix uteri when agreed rules for the compilation of the statistics have been observed.

The preparations for issuing the annual reports have been entrusted to an advisory committee consisting of Dr. J. Heyman, Radiumhemmet, Stockholm (Editor); Dr. A. Lacassagne, Radium Institute of the University, Paris; Lieut.-Col. A. B. Smallman, Ministry of Health, London.

The advisory committee, which is empowered to invite the collaboration of institutes and clinicians throughout the world, recognizes that its first annual report must necessarily be of an experimental character and serve as a guide for future work. It has consequently restricted the statements included in the report to those clinics and countries which were associated with the earlier work of the health committee.

The first report is concerned only with cancer of the cervix; the question of widening the scope of future reports so as to include, for example, analysis of material relating to the corpus uteri and the vagina is under consideration.

In a separate chapter the sources of error in the statistical assessment of the result of treatment are discussed. The chief of these are due to (1) the smallness of the samples for analysis, and (2) the lack of comparability between the clinical material analysed at the co-operating clinics.

In order to meet the difficulty caused by the smallness of the samples, the following procedure has been adopted: For samples containing fewer than 15 cases, percentages are not calculated; for samples containing from 15 to 100 cases, percentages are printed in ordinary type, and for samples relating to 100 or more cases, in black type.

Attention is drawn to the fact that comparability is difficult to secure because of the dissimilar composition of the material at different clinics. Some clinics receive for treatment unselected material; in the case of others a varying degree of voluntary or non-voluntary selection takes place.

It is pointed out that these two sources of error must be reduced to a minimum before it is possible to assert that differences between the results at different clinics are due to differences in the methods of treatment employed.

In comparing the figures given in this first report, the above sources of error should be kept in mind.

The committee has adopted certain rules which collaborators are expected to observe regarding cases which should be included in or excluded from the statements.

Further, two series of tables and relevant notes have been submitted, aiming at a uniform presentation of

the material reported and at a uniform method of calculating the result of treatment. The first series is intended for the annual statements relating to cases treated in 1930, the second for indicating the results obtained at an earlier period.

The collaborators' statements of the results of radiotherapy in cancer of the cervix in 1930 and previous years constitute the main part of the first annual report.

Statements have been submitted by:

1. The 'Centre des tumeurs de l'Université de Bruxelles', Belgium (contributed by Professor J. Muroch).
2. The Liverpool Radium Institute, England (contributed by Dr. P. Malpas).
3. The Marie Curie Hospital, London, England (contributed by Dr. Elizabeth Hurdon).
4. The Radium Centre for Carcinoma of the Uterus, London County Council, England (contributed by Sir Conyns Berkeley).
5. The 'Institut du Radium de l'Université de Paris', France (contributed by Dr. A. Lacassagne).
6. The 'Radiumhemmet', Stockholm, Sweden (contributed by Dr. J. Heyman).

The committee takes the opportunity of inviting directors of clinics and others interested in this subject to communicate with the editor (Dr. J. Heyman, Radiumhemmet, Stockholm) with a view to their participation in the future.

The report has been printed in English and French, the official languages of the League of Nations.

ANNUAL REPORT OF THE INSTITUTE FOR MEDICAL RESEARCH, FEDERATED MALAY STATES, FOR THE YEAR 1936. BY R. LEWTHWAITE, ACTING DIRECTOR

RESEARCH has been undertaken in many directions, old and new. Established investigations have progressed further towards their culmination; investigations newly begun embrace such problems as filariasis, the menace of the rat, nutrition, and certain aspects of the anti-larval action of oils.

Routine work has increased considerably; and, partly as a counter-measure, the personnel of the division of chemistry is to be increased by the addition of one chemist, now being recruited in Britain. With increasing knowledge in the field of medicine and its many related sciences, more and more is asked of this institute as to the quantity, refinement and variety of its routine work. Such requests cannot be refused, by reason of their importance to the public. Yet they encroach gradually on research work, by which the merits of the activities of this institute must primarily be measured, and which therefore can only be maintained by addition to the qualified personnel, such as has here been readily granted.

In the division of bacteriology there has been much re-organization consequent on an increase in the material submitted for routine examination. The introduction of the small screw-topped bottle for culture media has proved most useful both in effecting economy of labour and space, and in securing more successful cultural results.

Progress reports on investigations of various diseases are given, and interesting findings in routine observations are discussed. Laboratory findings in cases of agranulocytosis and glandular fever, diseases of rare occurrence in Malaya, are given, together with brief notes from the literature.

The outstanding feature of the work of the division of chemistry has again been the remarkable diversity of the problems with which it has been confronted. It will be seen from the chief chemist's report that assistance has been given to nine Government departments, in addition to the co-operation given to other divisions of this institute. Much of this type of work is far from being pure routine; a glance only at the variety of examinations made for the police department suffices to indicate the inter-play of intellect, imagination and intuition essential for the solution of the problems entailed thereby.

An investigation of practical economic application was that concerning the carotene content of four grades of Malayan palm oil.

The entomologist has continued his collaboration with the malaria research officer in the latter's field experiments in clinical prophylaxis. During these investigations a suggestion made by Professor Gater that two, possibly three, different species of mosquitoes have hitherto been identified as *A. umbrosus* was investigated by the entomologist in collaboration with Professor Gater. The findings indicated that the suggestion was well founded; and reference is made to the problems arising therefrom.

In order to extend our knowledge of the biology of anophelines in relation to the transmission of malaria to Kampong areas, three investigations are in progress; and the results already available are discussed at some length.

An investigation, begun last year, to test the efficiency of a new anti-malarial oil has continued. Early results indicate that an improved mixture has been obtained; but further results are awaited before conclusions are drawn.

The entomologist has begun an investigation into the problem of filariasis in Malaya; collaborating with him is Dr. J. J. C. Buckley, of the Department of Helminthology at the London School of Tropical Medicine. The investigation is at present concentrated on one area on the Bernam river (the boundary between Selangor and Perak) where a village and an estate have for some time been known to be endemic centres of elephantiasis. Recently an extensive area of adjacent jungle has been felled, drained, and planted with paddy by an immigrant labour force; and it is important to know what is the probability of the disease spreading to this force. The disease is endemic in certain parts of Malaya, in coastal and riverine areas. In other parts of the world, India, Africa, and the West Indies, the disease has proved a scourge that has seriously affected labour. For the development of rice growing, such as is occurring in certain of the above areas, the disease may become an important factor in success or failure. At present the prevention and treatment of filariasis leave much to be desired, but there is the prospect that with investigation and experimental work valuable results may be achieved. In the report of the entomologist will be found the early results of four lines of investigation.

The malaria research officer has continued investigations in clinical prophylaxis begun at the instance of the League of Nations' Malaria Commission, being part of a comprehensive trial of prophylactic treatment under different economic, climatic and racial conditions. The efficacy of atabrin as a prophylactic has been amply demonstrated in large-scale field experiments. That the drug may cause occasional severe reactions is well known, and experiments are still in progress to determine the optimum prophylactic dose. Collateral extensive experiments with prophylactic quinine are being carried out to afford a direct comparison of both the efficacy and cost of the two methods. An interim report is given. Other malarial remedies tested were atabrin-musonate, malarene, and a tablet of quinine specially

compounded to reduce cost without loss of efficacy. The summarized results are submitted.

Brief reference is made to the inception of a malarial survey of the Selangor coast area.

The research work of the division of pathology has been directed primarily to the problem of the preparation of a prophylactic vaccine for the tsutsugamushi disease. The source of virus used was infected material from animals experimentally infected; various methods of attenuation have been tried, and the more successful are being followed up. The investigation of an alternative and perhaps more hopeful source of virus, the tissue of infected mites, is projected; but must necessarily be protracted and laborious in view of the breeding problems entailed.

Five years of investigation has culminated in the establishment of the identity of the two diseases, rural typhus and tsutsugamushi. The typhus-like diseases of Malaya are thus reduced from three to two in number—a simplification to be welcomed in the study of the group of typhus fevers, ever enlarging throughout the five continents.

Further studies in the epidemiology of these fevers have been undertaken. The transmission of tsutsugamushi by the tick and the flea, and of urban typhus by the tick, has proved to be of doubtful occurrence, certainly of no importance. The transmission of tsutsugamushi by cannibalism amongst rats has proved possible, but the inferences are that it is of little importance epidemiologically.

An interesting finding has been that an infection of guinea-pigs with the *Spirillum minus*, in the absence of signs of typhus infection, could give a high agglutination of the OXK strain of *Proteus*; further investigation will be made as opportunity permits.

The report of the division of serology indicates the comprehensive range of examinations required of this division. In addition to a large volume of routine work, certain investigations have been made. A drug, 'T.A.D.D.', claimed to have amœbicidal value, was tested. A concentration method, recommended by certain British and Indian laboratories, has proved a very successful modification of the Friedmann-Zondek-Ashheim test for pregnancy.

Investigations concerning the blood-grouping of stains variously contaminated, continued from last year, have yielded results valuable in establishing criteria by which the results of these important medico-legal examinations should be interpreted.

The large volume of routine examinations reported from the Ipoh Branch Laboratory indicates how successfully this laboratory serves the dual purpose of relieving the parent laboratory at Kuala Lumpur of hampering routine and obviating delay in laboratory diagnosis for the hospitals of Perak. The officer in charge of the Branch Laboratory from May to December carried out tuberculin reactions on people of different race and age groups; and his results to date are given in summary.

The activities of the lymph station proceeded uneventfully throughout the year.

A brief reference is made to the inception of an investigation of rat viruses.

[This abstract from the director's general review will indicate the numerous lines of research that are being undertaken. It is unfortunately not possible to abstract these in detail, but specialists in the various branches are referred to the reports of the divisions from which they will obtain valuable information.]

ANNUAL REPORT OF THE SANITARY BOARD. BENGAL, FOR THE YEAR 1936. PUBLIC HEALTH DEPARTMENT, GOVERNMENT OF BENGAL

It is a satisfactory feature of the year under review that although financial stringency prevented Government from making the usual grants from provincial revenues towards the cost of municipal sanitary projects, the municipal boards, as a whole, were able to devote greater attention to the problems of water-supply, sewerage and drainage in urban towns, and continued to finance such projects by means of loans

and local contributions. As a result, there was a considerable expansion of the work of the engineering branch of the public health department during the year and a great deal of progress was made in investigations into and preparation of new water-supply, drainage, sewerage and other sanitary schemes.

The department continued to render valuable assistance to the municipalities and other local authorities in the shape of inspection and advice as well as of supervision, where found necessary or when called upon to do so. In particular, the department was called upon to examine and approve schemes of water-supply based on tube-wells proposed to be financed by district boards out of loan funds, as Government were satisfied that owing to faulty methods of construction and want of attention to the details of maintenance, there had been, in the past, a considerable waste of public money when such schemes had been undertaken and financed out of district funds or grants and loans from Government.

Government desire to invite particular attention to paragraph 18* of the report of the Chief Engineer, Public Health Department, and trust that municipalities intending to undertake water-supply projects for their towns will readily agree to have their schemes designed on the decentralized storage system of distribution recommended by the chief engineer, in view of the relative advantages of this system—

- (a) as providing a better waste of water in public
- (b) as ensuring protection against the risk of contamination of such supplies.

The sanitary board, the membership of which increased from 15 to 16, held seven meetings during the year under review and examined various projects of sanitary engineering before their submission to Government. The board also considered the reports of inspection made by the departmental officers and reviewed periodical reports on the analysis of samples of water from various sources in the province and suggested remedial measures, where necessary. They also advised Government in regard to the control of malaria—particularly in undertaking anti-ludlowii survey and control measures in the vicinity of Calcutta.

During the year, the board formed a sub-committee to investigate the possibilities of extending the system of water-supply by tube-wells for irrigation purposes.

* *Decentralized storage system.*—All new schemes of water-supply are being carried out on the decentralized storage system of distribution. Three town supplies are already operating on the system, and two more will come into action very shortly. It is now clearly demonstrated that the great difficulty in tropical water-supplies, viz, waste of water through taps left running, can be overcome by this method. It is also now clear that in several ways a water-supply is better protected from pollution by this system. A fertile source of pollution of water in the old type of distribution system is the leaky joint at the bottom of a standpost which has worked loose, dirty water being sometimes drawn in during the period of no pressure in the mains. The street tanks of the decentralized storage system cannot work loose, and the discharge point from the mains is 7 feet above ground inside the tank at the top. No dirty water, nor even dust, therefore, can possibly be drawn in. The application of the system to existing water-supplies is the problem which is now being faced. A code of rules for transformation of house connection from the old system to the new has been approved by Government and one municipality passed a resolution adopting it. But very little progress beyond that has so far been made. The chief difficulty in the way is the failure on the part of municipal commissioners to realize that some form of control of waste must be applied in order to have efficient distribution of water. Some seem to prefer to muddle along on the old system whereby the favoured few get as much water as they want while the bulk of the people get little or none. (Paragraph 18 of the Report of the Chief Engineer, Public Health Department, Bengal, for 1936.)

Correspondence

DEVELOPMENT OF HEALTH EDUCATION WORK IN UNITED PROVINCES

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—I write for the information of readers who may be interested in the article entitled 'Development of Health Education Work in United Provinces', which was published in the *Indian Medical Gazette* of October 1937, that the averages of weight and height for various ages in United Provinces which are given in a schedule in the article are based on the records of over 10,000 school boys.

Yours, etc.,
A. HAMID,
Assistant Director of
Public Health.

HYGIENE PUBLICITY BUREAU,
LUCKNOW,
6th December, 1937.

Service Notes

APPOINTMENTS AND TRANSFERS

COLONEL N. M. WILSON, O.B.E., to act as Surgeon-General with the Government of Madras, with effect from the afternoon of the 15th September, 1937.

The Governor is pleased to appoint Colonel P. S. Mills, Inspector-General of Civil Hospitals, Bihar, as Surgeon-General with the Government of Bengal, *vice* Major-General D. P. Gail, K.H.P.

Lieutenant-Colonel C. M. Plumtre, Acting Superintendent, Government Hospital for Women and Children, Madras, and Professor of Midwifery, Medical College, Madras, to be Principal, Medical College, Madras, with effect from the date of taking charge, *vice* Lieutenant-Colonel C. Newcomb, retired.

On return from leave Lieutenant-Colonel M. L. Puri resumed charge of his duties as Civil Surgeon, Rawalpindi, with effect from the 1st October, 1937.

On return from leave Lieutenant-Colonel P. A. Dargan resumed charge of his duties as Civil Surgeon, Amritsar, with effect from the 4th October, 1937.

On return from leave Lieutenant-Colonel C. J. Lodge Patch, M.C., resumed charge of his duties as Medical Superintendent, Punjab Mental Hospital, Lahore, with effect from the 15th October, 1937.

Lieutenant-Colonel D. Clyde has returned from leave *ex-India*, and has been posted as the Civil Surgeon of Lucknow, from 11th October, 1937.

Lieutenant-Colonel S. L. Bhatia, M.C., is appointed as Principal, Grant Medical College, and Superintendent, J. J. Group of Hospitals, Bombay, with effect from the 27th October, 1937.

On transfer from Multan Lieutenant-Colonel A. S. Fry assumed charge of the Office of Civil Surgeon, Simla East, on the forenoon of the 28th October, 1937, *vice* Lieutenant-Colonel B. Gale, proceeded on leave.

Lieutenant-Colonel B. F. Eminson resumed charge of the Office of Civil Surgeon, Hyderabad, Sind, with attached duties, with effect from the 30th October, 1937.

Lieutenant-Colonel R. A. Logan, Civil Surgeon, Amraoti, is reverted to military employment from 11th November, 1937, and posted to the Indian Military Hospitals, Lahore, as Second in Command.

Lieutenant-Colonel J. E. Ainslev returned from leave and assumed charge of the Office of Civil Surgeon, Amraoti, from 11th November, 1937.

Major A. I. Cox to rejoin, on return from leave, the appointment of District Medical Officer, Coimbatore, and Superintendent, Government Headquarters Hospital, Coimbatore.

Major B. N. Hazra made over charge of the Barisal Jail to Dr. M. Gupta in the afternoon of the 6th September, 1937, the latter again made over charge of the jail to the former in the forenoon of the 28th September, 1937.

On return from leave Major J. J. Beausang resumed charge of his duties as Civil Surgeon, Sargodha, with effect from 7th October, 1937, *vice* Captain P. C. Dutta, who became supernumerary to the number of officers provided with appointments.

Major K. S. Fitch made over charge of the Hooghly Jail to Dr. J. M. Mukherji, on the forenoon of the 10th November, 1937.

Major S. Annaswami made over charge of the Alipore Central Jail to Lieutenant-Colonel M. Das, M.C., on the forenoon of the 19th November, 1937.

Captain F. W. Allinson, Civil Surgeon, Midnapore, has been appointed temporarily to act, in addition to his own duties, as Superintendent of the Midnapore Central Jail, with effect from the forenoon of the 30th September, 1937, until further orders.

On return from leave Captain B. Temple-Raston resumed charge of his duties as Civil Surgeon, Jhelum, with effect from the 12th October, 1937.

Captain A. M. Sheridan has been transferred from Lucknow to Jhansi, where he took over charge on the 16th October, 1937.

Captain C. B. Miller, Resident Medical Officer, J. J. Hospital, Bombay, is appointed to officiate as Surgeon to His Excellency the Governor of Bombay, with effect from the 30th October, 1937, pending further orders.

Captain F. W. Allinson made over charge of the Midnapore Central Jail to Major S. Annaswami on the forenoon of the 26th November, 1937.

Captain A. M. Sheridan has been transferred from Jhansi to Cawnpore, *vice* Major W. Aitchison, proceeding on leave from 4th December, 1937.

LEAVE

The Governor is pleased to grant leave on average pay for 6 days to Major-General D. P. Gail, K.P.R., Surgeon-General with the Government of Bengal, preparatory to retirement, with effect from the 10th November, 1937, and in continuation leave on average pay for 4 months and 25 days from the 16th November, 1937.

Lieutenant-Colonel E. C. A. Smith, Superintendent, Central Mental Hospital, Yeravda, is granted leave on average pay for 7 months and 28 days, with effect from the 1st October, 1937.

Lieutenant-Colonel B. Gale, Civil Surgeon, Simla East, is granted combined leave for 5 months and 7 days, with effect from the 27th October, 1937 (afternoon).

PROMOTIONS

Majors to be Lieutenant-Colonels

A. V. Lopes. Dated 2nd November, 1937.

J. H. Barrett. Dated 2nd November, 1937.

I. S. Nalwa. Dated 16th November, 1937.

Captain to be Major

B. D. Khurana. Dated 28th October, 1937.

RETIREMENTS

Colonel C. H. Reinhold, M.C. Dated 16th November, 1937.

Lieutenant-Colonel C. Newcomb, C.I.E. Dated 3rd October, 1937.

Notes

'WELLCOME' BRAND SULPHONAMIDE-P

FOLLOWING the introduction of 'Tabloid' Sulphonamide-P (p-aminobenzenesulphonamide or sulphaniilamide) for the oral treatment of streptococcal and other infections, Messrs. Burroughs Wellcome and Company now issue the medicament in a fine crystalline powder as 'Wellcome' brand Sulphonamide-P, in bottles of 25 and 100 grammes. The 'Wellcome' brand product is intended for both parenteral and oral administration.

Recent investigations have considerably broadened the therapeutic indications for Sulphonamide-P. In addition to its established value in hæmolytic streptococcal infections (puerperal septicæmia, erysipelas, scarlet fever with complications, tonsillitis, etc.), there is now justification for its trial in cases of meningococcal meningitis, and *Bacillus coli*, *B. ærogenes* and *B. proteus* infections of the genito-urinary tract. Laboratory experiments also indicate that the drug may be of use in typhoid and paratyphoid fevers, and in staphylococcal septicæmia or infections; clinical experience for this group of infections is at present small.

'CELLOPHANE'

WE have received a letter from the British Cellophane Company, pointing out that in our issue of September last year we printed the word *cellophane* a number of times. This company points out that in this paper 'Electrodialysis in the Purification of Concentrated Serum Antitoxin' by Nirmala Pada Chatterjee, the word *Cellophane* is used in a generic sense to denote transparent cellulose sheeting generally.

'We wish to point out, however', they add, 'that the word *Cellophane* is not a generic term, but that it is the registered trade mark, also in British India, of British Cellophane Limited, and denotes the brand of transparent cellulose sheets and films manufactured and supplied by this company.'

Its use in the manner employed in the article in question is thus both erroneous and misleading.

We are naturally pleased to see references to our *Cellophane* cellulose film in the press; but our tacit acquiescence in misuse of our registered trade mark might eventually endanger our rights thereunder.

Publishers' Notice.

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to '*The Indian Medical Gazette*', Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers (if available) for the previous year Rs. 2-8 each, and all other back numbers Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, nor creased, in transit.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

GASTRIC ACIDITY IN HEALTH AND DISEASE IN INDIA

By L. EVERARD NAPIER, M.R.C.P. (Lond.)
R. N. CHAUDHURI, M.B. (Cal.)

and

M. N. RAI CHAUDHURI, M.B. (Cal.)

Department of Tropical Medicine, School of
Tropical Medicine, Calcutta

THE literature dealing with the findings of gastric analysis is voluminous, but satisfactory standards of normal gastric acidity among Indians have so far been lacking.

Until recently, it has been stated from time to time that the acid secretion in Indians living

Apperly (1936) claimed that in Australia he had found that the gastric acidity varied according to the distance from the equator, and that it was also less in the summer than in winter. He further suggested that it was always low in anæmia. This is entirely contrary to our, and other workers', experience.

Rao (1937) carried out 100 gastric analyses on normal Indian males in Southern India and found a high level of acidity (figure 4).

The present investigation

In order to get further evidence, we have tabulated the results of all the gastric analyses that had been done in the Tropical Diseases Hospital during the last 18 months; these were all done in the department of tropical medicine by one of us.

Fig. 1.—Mean readings and standard deviations in 38 cases of asthma.

in India is lower than that in Europeans, living either in hot climates or in temperate zones.

Previous work

Some twenty years ago, McCay in Calcutta did some work on this and reported that the gastric acidity was low in rice-eating Indians.

Dr. S. Bhattacharyya (1933) did a number of analyses on normal Indians and reported the acidity as low.

Dharmendra and Napier (1935) and Napier and Dharmendra (1936) found that in asthma, mostly among Indians, the general level of acidity was higher than the normal of the textbooks whereas other workers in Europe had found the acidity lower in asthmatics (figure 1). They believed that there was no constant change and that the level was much the same as in normal Indians.

Napier and Das-Gupta (1935) found that in normal Indians in Calcutta (figure 2) the mean acidity level was distinctly higher than that shown in the textbooks, and that that of so-called 'normal' tea garden coolies (figure 3) though not so high was nevertheless higher than the normal European standard.

These cases cannot, however, be regarded as normal individuals; some of these patients were suffering from anæmia, others from gastro-intestinal disturbances, and yet others were persons undergoing a routine examination for symptoms unconnected with the gastro-intestinal tract.

The technique

The alcohol test meal was used in this series of cases. Our reason for preferring this to the oatmeal gruel was the various disadvantages frequently encountered in the latter method. For instance, many patients found it very difficult to swallow a pint of tasteless gruel with a tube in the mouth. A good deal of time and trouble is expended in preparing a meal, and sometimes it was difficult to draw the fluid, which was thick, through the tube. Further a pint of it is sufficient to dilute the gastric juice very appreciably and to lower the readings, at least during the first hour. With the alcohol meal most of the disadvantages of the gruel are overcome. The 'meal' can be kept in stock ready for immediate use; it is passed directly into the stomach through the tube; the patient does not have to taste and swallow it; there is

little dilution of the gastric juice; the fluid obtained is a clear one; and alcohol being an efficient gastric stimulant promotes the secretion satisfactorily.

The argument that it is not a natural stimulant has been used, but this would apply to most of the gruel meals devised. Even if it is not enjoyed by the average patient, the alcohol is at least not repulsive to him and there is no psychological inhibition.

One hundred c.cm. of a 7 per cent alcohol solution in distilled water are used as the 'meal'. After the fasting contents have been withdrawn, the meal is injected and subsequently samples of the contents, about 10 c.cm., are obtained

have been classified under the following headings :—

- | | |
|---------------------|---|
| I Hyperchlorhydria | Over 65 c.cm. of N/10 NaOH per 100 c.cm. |
| II Normal range | High—over 45 but under 66.
Average—25 to 45.
Low—under 25 but not below 10. |
| III Hypochlorhydria | Below 10 units. |
| IV Achlorhydria | Tested with histamine—
Without acid response (a).
With acid response (c).
Not tested with histamine (b). |

The above has been the grouping more or less arbitrarily adopted by the senior writer for some time, as a result of his experience in

Fig. 2.—Normal Indians in Calcutta.

every fifteen minutes up to a maximum of 10 specimens. The biochemical investigations are carried out in the usual manner, by titrating a measured volume of each specimen in turn

Fig. 3.—Assam coolies: males and females.

against a decinormal caustic soda solution, using Topfer's reagent as the indicator. The resulting figures are plotted on charts drawn in the form suggested by Bennett and Ryle. We shall only consider the free acid here.

The clinical material

Gastric analysis by this method was performed in a series of 209 cases, and the results

India. It is interesting to compare it with that of Bell (1922) to whose paper his attention has only recently been drawn. The two groupings are contrasted in the following table (I).

Fig. 4.—Normal Indians in Southern India; range.

Our figures are slightly but distinctly higher than Bell's; for example, we look upon a maximum acidity of below 25 c.cm. as low, whereas Bell requires it to be below 20 c.cm.; we place the mean normal zone between 25 and 45, whereas Bell considers any figure above 30 as high; and his criterion for hyperacidity is 60 c.cm. against our 65 c.cm.

TABLE I

Groups	Type	Authors'	Bell's
I	Hyperchlorhydria	Over 65 c.cm.	Over 60 c.cm.
IIa	High normal ..	Over 45 c.cm.	Over 30 c.cm.
IIb	Normal ..	25 to 45 c.cm.	Under 30 c.cm.
IIc	Low normal ..	Under 25 c.cm.	Under 20 c.cm.
III	Hypochlorhydria	Under 10 c.cm.	Under 10 c.cm.
IV	Achlorhydria ..	No free HCl.	No free HCl.

In the series were included Indians, Europeans and others, both males and females; this fact has been utilized to compare gastric findings in different racial groups. The patients have been divided into the following racial groups :—

- (1) Europeans,
- (2) Indians from Bengal and Bihar,
- (3) Indians from other provinces, and
- (4) other classes including Anglo-Indians and Jews.

They have been further subdivided and considered according to their sex and age.

Table II shows the results of gastric analysis in different groups according to the sex. A better idea of the 'acid state' in the various racial groups can be obtained from table III showing the percentage incidence of the different acid states; in this table (III) for the sake of simplicity and to avoid the sex factor we have included only the male cases. It shows that the percentage of hyperchlorhydria was largest among the Europeans and other males, the non-Indian groups, and that Bengal Indians came very close to them. The acidity was within the normal limits in the majority of the Bengalis, in spite of the fact that many of them were suffering from conditions which usually give rise to hypo-acidity. The percentage of hypochlorhydria also was highest among the Europeans, but there was no case of complete achlorhydria amongst them, so that the deficient-acid group, combined hypo- and achlorhydria, was only slightly greater amongst Europeans than amongst Bengalis and less than in the other Indian series. Indians from other provinces show a much lower acidity all round, and by far the highest incidence of achlorhydria.

TABLE II

Showing the distribution of cases in the various acid groups, according to their race and sex

	Sex	Number of cases	Hyperchlorhydria 65 +	NORMAL RANGE			Hypochlorhydria 10 —	ACHLORHYDRIA		
				High 45 +	Medium 25-45	Low 10-25		Even after histamine	Not tested & histamine	& acid response after histamine
Europeans ..	Male	20	5	3	7	1	4
Do. ..	Female	31	1	5	8	5	6	..	5	1
Indians (Bengali and Behari) ..	Male	89	16	20	21	16	7	2	6	1
Do. ..	Female	16	1	1	5	3	3	2	1	..
Indians (other provinces) ..	Male	28	1	4	6	9	2	2	2	2
Do. ..	Female	6	1	1	2	1	1
Other non-Indians ..	Male	10	2	2	4	1	1	1
Do. ..	Female	9	1	2	2	2	1	1

TABLE III

Showing the figures for males in table II on a percentage basis

	Hyperchlorhydria 65 +	NORMAL RANGE			Hypochlorhydria 10 —	ACHLORHYDRIA		
		High 45 +	Medium 25-45	Low 10-25		Even after histamine	Not tested & histamine	& acid response after histamine
Europeans ..	25	15	35	5	20
Bengal Indians ..	17.5	22.4	23.5	17.5	8.4	2.4	7.2	1.1
Other Indians ..	3.5	14.2	21.5	32.4	7.1	7.1	7.1	7.1
Others ..	20	20	40	10	10

Table IV and figures 5, 6 and 7 show the means and standard deviations in male hospital patients, Europeans, Bengal Indians, and other Indians, respectively.

would, by the same process of deduction, be about 4 per cent. It seems to indicate that it is not more common in India than in Europe and America.

TABLE IV

Shows the mean and standard deviation of the gastric acidities at various intervals for both groups of Indian and European males, separately

		F. S.	¼ hr.	½ hr.	¾ hr.	1 hr.	1¼ hrs.	1½ hrs.	1¾ hrs.	2 hrs.
Bengali males	Mean ..	14.6	12.9	24.6	29.8	26.4	25.5	23.2	20.5	20.0
	Standard deviation	± 19.9	14.7	23.1	25.8	23.8	24.9	25.5	23.8	24.6
Other Indians	Mean ..	9.3	6.9	14.9	17.9	17.8	15.2	12.3	10.5	11.4
	Standard deviation	± 19.5	10.7	14.7	18.2	19.8	16.4	14.6	14.3	17.7
European males	Mean ..	12.6	24.2	31.1	31.8	30.7	27.9	23.8	22.6	14.8
	Standard deviation	± 16.9	32.6	30.4	27.2	29.0	30.2	24.5	26.2	20.5

Achlorhydria

Altogether in 26 cases there was complete absence of free hydrochloric acid after the alcohol meal: males—15 and females—11. Histamine 0.25 to 0.5 mgm. was given hypodermically at a second test meal after the second post-prandial sample had been taken, in 12 cases; in six of these there was some secretion of free acid in the samples taken after the

Fig. 5.—European males.

histamine administration, but in the other six there was none. Fourteen cases were not tested with histamine.

According to the table given by Harrison (1937), achlorhydria occurs in 4 per cent of normal persons; other workers have placed the percentage higher. If, in our series, the response to histamine in the 14 untested cases be considered to be 50 per cent, as in the 12 tested cases, then the total incidence of achlorhydria is 13 out of 209 cases, which is less than 6 per cent. Achlorhydria is a complication in many pathological conditions; in the anæmic cases it was over 22 per cent (*v.i.*). If these are excluded, the incidence of complete achlorhydria

Fig. 6.—Bengali males.

Fig. 7.—Other Indian males.

Sex

Table V shows the distribution, amongst the four main acid groups, of males and females separately.

TABLE V

	MALES		FEMALES	
	Num- ber	Per cent	Num- ber	Per cent
Hyperchlorhydria	24	16.4	4	6.5
Normal range	94	63.9	37	59.7
Hypochlorhydria	14	9.5	10	16.1
Achlorhydria	15	10.2	11	17.7

This table shows that the incidence of hyperchlorhydria was three times as common amongst males as females and conversely that hypo- and achlorhydria were nearly twice as common amongst females as amongst males.

Age

Table VI shows the distribution of males according to their 'acid state' and age. The influence of age is shown better if the cases are arranged into the four main acid groups and the percentage incidence calculated as in table VI(a).

increases. Conversely, if the low-acidity groups are taken together, the incidence in these groups decreases with age.

Fig. 8.—English standard range (Bennett, 1923).

Analysis according to diagnosis

We next attempted to classify the cases according to the diseases from which they were suffering in relation to their gastric acidity. The diagnosis as written on their case sheets at

TABLE VI

Showing the distribution of males according to their age and 'acid state'

	40 YEARS AND OVER					30 YEARS AND OVER					20 YEARS AND OVER					BELOW 20 YEARS				
	European	Bengali	Other Indians	All Indians	Total	European	Bengali	Other Indians	All Indians	Total	European	Bengali	Other Indians	All Indians	Total	European	Bengali	Other Indians	All Indians	Total
Hyperchlorhydria	2	6	1	7	9	2	6	0	6	8	1	3	0	3	4	..	1	0	1	1
High	2	3	0	3	5	1	11	3	14	15	0	5	1	6	6	..	1	0	1	1
Medium	4	4	2	6	10	2	7	2	9	11	1	9	1	10	11	..	1	1	2	2
Low	0	4	1	5	5	1	6	2	8	9	..	4	5	9	9	..	2	1	3	3
Hypochlorhydria	1	1	0	1	2	3	2	2	4	7	..	4	0	4	4	..	0	0	0	0
Achlorhydria not tested	0	3	0	3	3	0	1	0	1	1	..	2	2	4	4	..	0	0	0	0
Achlorhydria c alcohol	0	1	0	1	1	..	1	2	3	3	..	0	0	1	1
Achlorhydria c histamine	0	2	2	2	..	1	0	0	0

TABLE VI(a)

	40 YEARS OR OVER		30 YEARS BUT UNDER 40		20 YEARS BUT UNDER 30		UNDER 20 YEARS
	Number	Per cent	Number	Per cent	Number	Per cent	Number
Hyperchlorhydria	9	26.5	8	15.4	4	9.3	1
Normal range	20	58.8	35	67.3	26	60.5	6
Hypochlorhydria	2	5.9	7	13.5	4	9.3	0
Achlorhydria	3	8.8	2	3.8	9	20.9	1
	34	..	52	..	43	..	8

We can afford to ignore the youngest group as the figures are so small. With the increase of age the incidence of hyperchlorhydria steadily

the time of discharge was taken; table VII shows the result of this analysis, but a considerable amount of grouping has been done.

The only outstanding feature in this table is the very high incidence of achlorhydria in the anæmia group. Further division of this group into the different types would be interesting, but we do not propose to do this here. If this group is excluded, only 13 cases of achlorhydria

occur in 151 cases; this is an incidence of less than 9 per cent achlorhydria (to the alcohol meal).

The further division of the other three large groups is shown in table VIII.

TABLE VII
Cases grouped according to diagnosis and gastric acidity

	Total cases	Hyperchlorhydria	Isochlorhydria	Hypochlorhydria	Achlorhydria

In the case of gastric disorders, this subdivision is very unsatisfactory as it is obvious that in almost every instance the diagnosis had depended on the result of the gastric analysis itself; take, for example, the diagnoses hyperchlorhydria, hypochlorhydria, and achlorhydria, whereas the words gastralgia and dyspepsia were evidently used when the gastric acidity was normal. And even the diagnosis of 'ulcer' was probably influenced by a finding of hyperchlorhydria.

Analysis according to symptoms

We decided therefore to re-analyse these cases according to symptoms. For this re-analysis we excluded all the anæmia group and 11 other cases in which there was both definite clinical dysentery (i.e., blood and mucus in the stools) and a specific diagnosis of amœbie or bacillary dysentery, but otherwise took all patients who showed any prominent gastric or intestinal symptoms, including epigastric pain, flatulence, diarrhoea and constipation.

Of the 11 dysentery cases, 9 were within the normal range, one was hyperchlorhydric and one hypochlorhydric. The case-cards selected for re-analysis were grouped as follows (table IX) :—

(c) The high incidence (61.1 per cent) of disordered acid secretion in cases in which flatulence is a prominent symptom.

The high incidence of epigastric pain in cases with hyperchlorhydria is what one would expect.

The association of diarrhoea and low gastric acidity is also easy to understand, and it seems probable that the diarrhoea is secondary to the low acidity rather than *vice versa*. Flatulence is usually associated with fermentation and hypomotility which one would expect in low acidity, and the high incidence of flatulence in hyperacidity probably indicates air swallowing to relieve pain as an additional cause.

Time of acid peak

The cases were analysed according to the time of the acid peak in relationship to race and sex. In the whole series the acid peak occurred most frequently at $\frac{1}{2}$ hour, but in a large number of cases it was at the $\frac{1}{4}$ hour sample. There were no racial or sex differences. The time of development of the acid peak is much earlier in this series than in any British or American series reported.

TABLE IX
Cases grouped according to symptoms and gastric acidity

	Achlorhydria	Hypochlorhydria	Isochlorhydria	Hyperchlorhydria
Epigastric pain only ..	1	1	6	3
Pain + diarrhoea ..	1	1	9	1
Pain + constipation	8	6
Pain and flatulence ..	1	1	2	4
Pain, diarrhoea and constipation	2	2
Diarrhoea only ..	4	4	13	1
Diarrhoea and constipation ..	1	..	11	1
Constipation	2	3	..
Constipation and flatulence	1	..
Flatulence ..	1	1	4	3
TOTAL ..	9	10	59	21
Epigastric pain (all cases) ..	3	3	27	16
Diarrhoea (all cases) ..	6	5	35	5
Constipation (all cases) ..	1	2	25	9
Flatulence (all cases) ..	2	2	7	7

The noticeable points are as follows :—

(a) The high incidence (32.6 per cent) of hyperchlorhydria in cases in which pain was a prominent feature, or, to put it another way, the high incidence (76.2 per cent) of pain in cases of hyperchlorhydria.

(b) The incidence of low acid secretion, hypo- or achlorhydria, in cases where diarrhoea was the only prominent gastro-intestinal symptom. This was not so striking in those cases in which diarrhoea was associated with pain and/or constipation, but in this group the incidence of hyperchlorhydria was very low.

Other features of the acid curve

The initial fall of acidity due to the dilution of the gastric juice was naturally not as marked with the smaller alcohol meal as it is with the gruel meal. Further, in a number of cases it was absent altogether; presumably the stimulation of the gastric mucosa was sufficiently rapid to counteract the diluting capacity of the 'meal'.

Table XI shows the incidence of this initial fall in the different racial and sex groups. Only 15 per cent of European males showed an initial fall in the curve against over 40 per cent

TABLE X
Cases grouped according to time of peak of gastric curve

		'Fasting'	$\frac{1}{4}$ hr.	$\frac{1}{2}$ hr.	$\frac{3}{4}$ hr.	1 hr.	1 $\frac{1}{4}$ hrs.	1 $\frac{1}{2}$ hrs.	1 $\frac{3}{4}$ hrs.	2 hrs.	2 $\frac{1}{2}$ hrs.
Europeans	{ Male	1	3	5	3	3	2	1	2
	{ Female	1	..	5	6	5	2	1	1	3	1
Bengal Indians	{ Male	9	3	15	21	8	8	6	4	5	1
	{ Female	2	5	2	2	1	..	1	..
Other Indians	{ Male	2	..	6	6	4	1	1	1	1	..
	{ Female	1	1	1	2	..
Others	{ Male	2	..	1	1	2	2	1	1
	{ Female	3	..	1	1	2	1
TOTAL ..		18	6	35	44	26	18	12	10	12	2

TABLE XI

Showing separately the number of cases in each group in which there is an initial fall and a secondary rise in the acid curve

		Number in group	Number showing initial fall	Number showing secondary rise
Europeans	{ Male	20	3	9
	{ Female	31	2	10
Bengal Indians	{ Male	89	36	63
	{ Female	16	4	6
Other Indians	{ Male	28	6	11
	{ Female	6	1	2
Others	{ Male	10	4	6
	{ Female	9	3	3

amongst Bengal Indian males, the difference is considerable but not statistically quite significant as the numbers in the European group are small. Any difference that there is cannot be accounted for simply by the higher acidity in the European group because the percentage of initial falls is even lower in the female Europeans and is also comparatively low in the Other Indians group, in both of which the gastric acidity is very low. The same table shows the incidence of the secondary rise in the different groups, the highest percentage incidence is in Bengal Indian males, but there is little difference between the groups.

Fasting stomach contents

Table XII shows the amount of 'fasting' gastric secretion in 203 cases: in 6 cases the amount was not recorded. The mean amount in this whole series was 33.5 c.cm.; in 141 men

TABLE XII

Grouping of cases according to the amount of the 'fasting' content of the stomach

		FASTING CONTENT IN C.C.M.						
		Up to 20 c.cm.	21-40	41-60	61-80	81-100	101-200	Above 200 c.cm.
Europeans	{ Male	5	8	5	1	..	1	..
	{ Female	11	15	1	3	..	1	..
Bengal Indians	{ Male	34	28	11	7	..	4 (106, 150, 154, 200)	1 (255)
	{ Female	5	7	4
Other Indians	{ Male	4	15	5	1	1
	{ Female	2	3	1
Others	{ Male	2	6	2
	{ Female	5	3	1
TOTAL ..		68	85	29	12	2	6	1
PERCENTAGE ..		33.5	41.8	14.3	5.8	1.0	2.9	0.5

the mean was 35.7 c.cm. and in 62 women it was 29.0 c.cm.

In three-quarters of the cases there were 40 c.cm. or less of gastric secretion. There is a distinct difference between the men and women: in the former 72.5 per cent have a secretion of 40 c.cm. or less and in the latter the figure is 82.3 per cent. The difference (9.8 per cent) is just below the significance level (standard deviation = ± 6.5).

There is little difference in the amount of gastric secretion in the different racial groups.

The association of hyper-secretion and hyperchlorhydria

In table XIII the relationship of hyper-secretion and hyper-acidity is shown. In 28 cases of hyper-acidity, 11 show a secretion above 50 c.cm. in amount, and of the remaining 175 cases in which there is normal or deficient acid secretion only 20 show a secretion above 50 c.cm. The incidence of hyper-secretion in the hyperchlorhydric group is thus 39.3 per cent, whereas in the rest it is only 11.4 per cent. The difference, 27.9 per cent, is definitely 'significant', as the standard deviation is ± 7.3 per cent.

TABLE XIII
Showing the incidence of hyper-secretion in the hyperchlorhydric group

		Total number of cases	Number of cases in which fasting content is above 50 c.cm.

TOTAL ..		28	11

Summary

The current belief that the gastric acidity in Indians living in the tropical and sub-tropical parts of India is lower than that of Europeans living in temperate climates has been shown, by recent investigations on normal Indians at the Calcutta School of Tropical Medicine and elsewhere, to be incorrect.

Fractional gastric analysis, with alcohol as the test meal, was done in 209 hospital patients

suffering from a number of different diseases. The series was a mixed one as regards race and sex.

The standards which we adopted arbitrarily for applying the terms hyper- and hypochlorhydria in individual cases are slightly higher than those used by British physicians.

Amongst our hospital patients, Europeans show the highest mean acidity and the highest incidence of hyperchlorhydria, Bengalis come next, and the lowest acidity is seen in 'other Indians' most of whom were Punjabis; the latter group showed by far the highest incidence of achlorhydria. The significance of this is not clear. The Bengali group included by far the largest percentage of vegetarians who were all rice eaters.

It is known that in South India rice eaters are notoriously liable to peptic ulceration and that the wheat-eating Punjabi is much less so, but this does not explain the high incidence in the meat-eating European; most of these were well-to-do and possibly the high incidence of hyperchlorhydria in this class was a sequel to alcoholic and dietary indiscretions and the accompanying gastritis.

Achlorhydria is not common in non-anæmic persons in India; the incidence is apparently, as far as can be judged from the literature, about the same or a little lower than that in Europe and America.

Hyperchlorhydria occurred in 16.3 per cent of men against 6.4 per cent of women, and achlorhydria in 10.2 per cent of men against 17.7 per cent of women: the difference is not statistically significant in either case.

Hyper-acidity is more common in the higher age groups.

The highest incidence of achlorhydria occurred amongst patients diagnosed as anæmia; this is the universal experience but only one case of true pernicious anæmia was included in the series.

When the cases were analysed according to the symptoms, there were noticeable associations between epigastric pain and high acidity, and diarrhoea and low acidity, respectively.

The 'acid peak' occurred early, about three-quarters of an hour after the 'meal', in all groups; this can probably be accounted for by the more rapid action of alcohol, as compared with gruel, in stimulating acid secretion.

In only a few instances was there an initial fall in the acid curve in the European group, in the other groups this initial fall was more frequent.

The amount of 'fasting' gastric secretion was higher in men than in women, the mean being 35.7 c.cm. in the former and 29.0 c.cm. in the latter. The amount of 'fasting' gastric secretion was 'significantly' higher in the hyperchlorhydric cases; this is the usual finding.

THE RADIOLOGICAL EXAMINATION OF THE STOMACH AND DUODENUM

By G. GALSTAUN, M.A., D.M.R.E. (Cantab.), M.R.C.S.,
L.R.C.P. (Lond.)

Professor of Radiology, Medical College Hospitals,
Calcutta

THIS short outline is intended as a guide to the general practitioner. Radiology has in the past few years played an increasingly important part in the diagnosis of gastric and duodenal conditions. With improvements in apparatus the radiologist is now able to produce more and more accurate results. The reason of this is twofold. Firstly, with ample power now available in modern diagnostic units, exposures are reduced to speeds of the order of one-tenth of a second or even less than half of this. Secondly, by reason of methods of graduated and controlled compression, together with a device for radiographing appearances, the moment they are seen on the fluoroscope, much greater accuracy is attained. By means of these methods we are frequently able to demonstrate ulcer craters and other anomalies, which would otherwise be completely missed.

Case 1 is an example where by using an ordinary technique without compression the appearances of the stomach and duodenum were found to be fairly normal, whereas with the serial duodenal device, with controlled compression, a very distinct saccular structure was seen arising from the proximal portion of the second part of the duodenum. It was suggested that this might be a diverticulum, which was in fact found at operation. This is only one of many examples. In other instances, by this method I have been able to demonstrate very definite ulcers of which I saw no trace in the routine skiagrams of the stomach.

The rationale of any opaque meal examination consists of a delineation of :—

1. Outline.
2. Mucosal pattern.
3. Living structure.

The latter of course will be for the most part seen in the fluoroscope.

It is important that, in order completely to fill all crevices, the opaque meal be of a completely homogeneous nature and held in proper suspension. It should not be gritty. Grit may cause spasm. Many preparations are on the market, most of which fulfil these conditions. They all consist of barium sulphate in a very fine state of division, held in suspension by either a gum or some other suitable material and variously flavoured, more often than not with chocolate.

Usually for an examination of the stomach and duodenum no purgation is necessary. Where the patient is constipated, however, it is advisable to give a mild purgative, such as two drachms of compound liquorice powder some thirty-six hours before examination. It is essential that the patient does not go to the radiologist in a starving state. A starved stomach is usually in a state of spasm, rendering examination of the mucosa difficult, if not impossible. In order to avoid this I always advise my patients to have a couple of slices of bread and butter or toast, and a cup of tea from two to three hours before coming to be examined. In certain cases where spasm is seen to be present this can be relieved by a small dose of belladonna or an injection of atropine.

It is essential for the radiologist to be provided with an accurate history of the case. It is to be remembered that radiology is merely one link in the chain of diagnosis, though usually in these cases a very important link. Such futilities, as sending a patient with a brief note 'A photo of the stomach', should be avoided.

The first procedure in the x-ray examination consists of a general survey. The lungs should always be screened. Many cases of dyspepsia can be traced to a phthisical origin. The diaphragm should always be examined and any limitation in movement or fixation noted. It should be seen whether the liver is normal in size or enlarged. Such details as gas in the stomach or intestine should be observed. It may be necessary in a stomach already full of secretion to empty this.

Having completed this general survey the patient is given a small quantity of the barium emulsion. The stomach is then palpated with the gloved hand and the emulsion suitably splashed about the walls, held here and there as necessary so as to show as much as possible of the detail of the mucosa. Quite often an ulcer crater will be visualized in this way as a small residue with spider-like folds of mucous membrane converging on it. Such a residue will usually be found to be tender. Following this, films are taken with suitable compression by a cone so as to show the mucosal pattern.

After this a full pint of the barium emulsion is given and the following features noted :—

- (a) The general contour of the stomach.
- (b) Tone.
- (c) Peristalsis.

Diagrams showing the relative incidence of gastric ulcer and carcinoma.

Erect. Left antero-oblique.

- (d) Mobility.
- (e) Rate of emptying.
- (f) Any tenderness.
- (g) Spasm.
- (h) The presence of any ulcer niche or irregularity.

It is essential to examine the stomach in all positions, not forgetting that, in certain stomachs, particularly those of the transverse type, in order to visualize the duodenal cap it will be necessary to use the postero-oblique posture.

is extremely doubtful whether such a thing as a truly dropped stomach *per se* exists.

Mills in 1917 classified stomachs into three main groups:—

(a) *Sthenic*.—This, the normal J or 'fish hook' type of stomach, is found in 70 per cent of cases.

(b) *Hyposthenic*.—A stomach of low tone which does not grip its contents well and is usually placed at a lower level than normally, often hanging down in the pelvis. This type of

Case 2.—An example of 'niche and notch'. Ulcer of the lesser curvature and spasm.

The same case after three months after a course of Sippy diet and injections of Larostidin. Note the pointing of the ulcer crater and absence of spasm.

Case 3.—A very large ulcer at the lower end of the lesser curvature.

The same case at five hours.

Having examined the stomach we next turn to the duodenal cap, which is examined in an exactly similar manner.

An examination done five hours after the meal is always useful, as residues seen at this time are usually of some significance.

Types of stomach

It has been clearly understood for some years that the form taken by the stomach is largely a function of the subject's build or habitus. It

stomach is as a rule found in long, lanky subjects, often poor eaters. A five-hours' residue in such a stomach is not uncommon and like the stomach itself is certainly not pathological.

(c) *Hypersthenic*.—This type of stomach is usually of steer-horn shape, lying transversely across the abdomen, as textbooks of anatomy would have us believe the normal stomach does. It is found in subjects of broad and squat build. Tone is good. Peristalsis is increased, compared with that of the sthenic type of stomach.

Such stomachs have a relatively high acid content and their owners have good appetites. More often than not in this type, in the antero-postero position, the duodenal cap usually lies behind the pylorus, giving a superimposed shadow. It can be well seen, however, with an oblique positioning.

Internal structure

The mucous membrane of the stomach is thick and glandular. It is fixed along the lesser curvature and at the pylorus, being free elsewhere. The sub-mucous coat is lax allowing fairly free movement. The mucous membrane is thrown into multiple folds, small near the attachment at the lesser curvature, and more voluminous and deeper at the greater curvature.

At the lesser curvature is seen a hiatus in the oblique fibres of the musculature. This causes an irregular contraction forming in this situation a sort of canal—the 'Magenstrasse' of the Germans. No oxyntic cells are found here. It

Case 4.—Penetrating ulcer of the lesser curvature. The prone anterior position in which this skiagram was taken is often the best one to demonstrate this type of ulcer.

is in this locality that about 90 per cent of gastric ulcers occur.

The mucosal pattern of a normal stomach should flow in regular folds. Any marked irregularities in these folds must be inquired into. In cases of ulcer they are usually seen to be puckered up in a spider-like manner, the body of the spider being the ulcer crater. Various forms of chronic gastritis produce coarsening and irregularities of these folds.

Tone

The normal stomach should tend to grip its contents and not bulge. Peptic ulcer is commoner in hypo-tonic stomachs with low acid contents.

A 'long' type of stomach has been described by Hurst in which traction on the mesentery occurs. Radiological examination in these cases does not show evidence of any inflammatory lesion and the pain associated with them is, as one would expect, relieved by lying down.

Peristalsis

The waves of peristalsis initiated at the cardia flow towards the pylorus. At first slow and shallow, they gather speed and depth as they reach the pylorus.

Peristalsis is not to be confused with tone. It has been shown within recent years by Graham, Cole, and other workers that peristalsis is a function of the muscularis mucosæ, whereas tone is more the function of the muscular coats of the stomach.

Spasm

(a) *Cascade spasm*.—The stomach in these cases assumes the form of a cup at the cardia from which the meal flows into the pars media. For this reason this type has been called the 'cup-spill' stomach. In most cases this appearance is undoubtedly of spasmodic origin and the spasm is relaxed by belladonna.

Case 5.—Pyloric stenosis. Pre-pyloric ulcer crater demonstrated as a residue at five hours. Note the large stomach retention.

(b) *Spastic incisura, or regional spasm*.—This may be a reflex phenomenon or the result of an ulcer, usually in the opposite wall.

Fraenkel has described a series of cases of very early ulceration in the lesser curvature where, though no ulcer can be demonstrated radiologically, there is definite spasm with lack of peristalsis in a small section of the lesser curvature.

Post-operative adhesions may cause either true spasm or appearances simulating spasm in the stomach. It is sometimes a matter of difficulty on radiographic appearances alone to exclude malignancy in such cases.

(c) *Pyloro-spasm*.—Spasm of the pylorus is often caused by a pre-pyloric ulcer. It may, however, be found in some cases of duodenal ulcer and reflexly as the result of other abdominal inflammatory lesions. A. C. Jordan has described this condition as being often associated with other spasmodic conditions, such as cardio-spasm.

Emptying time

The rate of emptying of the stomach depends among other things on the nature of the food.

ingested. It is usually more rapid in the hypersthenic type of stomach. The stomach normally should be empty in five hours, but residues at six hours and more are not uncommon in hypotonia. This is not necessarily pathological. Where long retention is found in the stomach,

Case 6.—Carcinoma of the stomach involving the pylorus and most of the greater curvature.

pyloric stenosis may be suspected. In this condition it is extraordinary how long the stomach can retain its contents. There is a classic story of a patient at St. Bartholomew's Hospital suffering from pyloric stenosis who one day vomited a large bowl full of gastric contents. He stared for some time at the bowl and then exclaimed with some astonishment 'Ham! Ham!! I ain't had ham for a fortnight!'

Case 7.—Duodenal ulcer. Note the deformed cap with folds of mucous membrane converging on a crater and gas bubble on top. The second skiagram at five hours shows a residue in the crater.

Hyper-secretion

Hyper-secretion is easily seen on the fluorescent screen or skiagram by a less opaque fluid level lying over the dense barium emulsion.

Gastric ulcer

Russel Carman has estimated that 90 per cent of all gastric ulcers occur in the lesser curvature

between the cardiac orifice and the incisura angularis.

An ulcer crater may be seen on the fluoroscope or skiagram either as a small niche or as a large diverticulum-like structure, sometimes with a gas bubble on top. It may be seen as a large pyriform filling defect. The shape of the crater, if seen, will naturally correspond to the underlying pathology. It must be borne in mind however that owing to the heaping up of the mucous membrane around a gastric ulcer the size indicated in the skiagram is apt to be deceptive.

It has been mentioned before that gastric ulcers may be demonstrated by the spider-like converging folds of mucous membrane, showing in the mucosal pattern. A residue and tenderness over the suspected crater are always of significance. The fixation of the portion of the lesser curvature in very early ulcerative or pre-ulcerative states has already been mentioned.

A characteristic feature very often seen in association with an ulcer in the lesser curvature is spasm in the greater curvature opposite. In certain cases this spasm might involve almost the entire circumference of the stomach, producing a pseudo-hour-glass contraction. This, however, is not to be confused with the true hour-glass stomach, which is the result of chronic ulceration with cicatricial contraction. The true hour-glass contraction is always more marked in the lesser curvature, and has not the clearly-defined outlines of the pseudo-hour-glass contraction.

Where an ulcer previously under observation is seen to lose its rounded appearance and become conical or pointed, healing is indicated.

In these cases, too, the spasm opposite is considerably lessened or absent.

Pyloric ulcer or pre-pyloric ulcer

This type of ulcer is usually difficult to demonstrate. They are often shallow and not cup-like as those in the lesser curvature; as a rule they cause pyloro-spasm, with stenosis,

which may be really due to cicatricial contraction, or more often as the result of spasm.

It will be almost impossible to demonstrate a pre-pyloric ulcer with the stomach full of opaque meal. In these cases, one has to rely on indirect appearances and largely on the mucosal pattern. Indirect evidence is furnished by the spasm and the often dilated stomach, which is the result of spasm or stenosis.

Gastric carcinoma

The differential diagnosis between ulcer and carcinoma of the stomach is very often impossible in the early stages of the latter by purely radiological methods. In these cases it is essential carefully to consider the whole clinical picture. Quite a few cases have been reported where what appeared at the first examination to

Case 8.—Ulcer crater in the duodenal cap.

be a simple ulcer in the lesser curvature or pre-pyloric region has turned out on subsequent examination at a later period to be a cancer.

The radiological signs of carcinoma of the stomach consist of an irregular and constant filling defect often having crescentic impressions such as those a thumb might make on putty. There is always a lack of peristalsis in the affected area owing to the destruction of the underlying muscularis mucosæ.

Where the growth is at the pylorus an irregular conical narrowing of the lumen will be seen. In the ring type of carcinoma of the pylorus, emptying of the stomach is rapid as though the meal was passing through a rigid pipe. In these cases an associated ileus of the second part of the duodenum is seen in the majority of cases. Where the growth is not completely annular, on the contrary, spasm may be induced at the pylorus.

The question of spasm in the stomach is often very confusing, in doubtful cases, alkalis and belladonna or sometimes gentle palpation while screening will clarify things. The relative regional incidence of gastric ulcer and carcinoma is seen in the accompanying diagrams. It will be seen that whereas the vast majority of gastric ulcers are situated in the lesser curvature, the seat of election of gastric carcinoma is in the pyloric region. In carcinoma of the cardiac end of the stomach, the chief clinical symptom

is dysphagia, due to stenosis at the cardiac orifice. Examination shows a filling defect at the cardia, sometimes invading the lower end of the œsophagus.

Diverticulum of the stomach

These saecular excrescences are not very common. They usually occur high up in the cardia, and have a smooth outline with no tenderness or associated spasm. They often remain filled for a considerable time.

Leather bottled stomach

This condition consists of a fibrous carcinomatosis. The stomach presents a rigid steer-horn appearance with an almost or absolutely complete lack of all peristalsis.

The same case at five hours. A very small stomach residue seen, and a distinct residue in the ulcer crater.

Gastric syphilis

This is characterized by a contracted stomach with thickened, hypertrophied and irregular folds of mucous membrane. Rigidity is usually present. There is no palpable tumour felt in

Case 9.—Penetrating ulcer of the duodenum.

these cases. Often there may be an hour-glass deformity with no demonstrable ulcer crater.

Tuberculous disease of the stomach

This is exceedingly rare. The radiographic appearances are similar to those of syphilis.

Polyposis

These growths show in the skiagram as irregular rounded filling defects, usually with a smooth outline. In extensive cases the diagnosis from malignant disease may be difficult so far as radiographic appearances alone are concerned.

Foreign bodies

Many types of foreign body may be found in the stomach. One sometimes causing a good deal of trouble in diagnosis is a hair ball. I have on more than one occasion found a Ryle's tube retained in the stomach.

Diaphragmatic hernia

As a rule this usually presents no difficulty in diagnosis. Prior to the giving of the opaque meal probably a large irregular collection of air will be visualized in the thorax. On giving the

Case 10.—Penetrating ulcer of the duodenal cap. Right antero-oblique position.

opaque emulsion it will be seen that the stomach or even more has herniated through the diaphragm into the thoracic cavity.

THE DUODENUM

The first part of the duodenum, immediately beyond the pyloric ring, is seen in opaque meal examinations as a cap-shaped structure, rather like a monk's hood. Hence the term 'duodenal cap'. Morphologically this is a part of the stomach. Ninety per cent of all duodenal ulcers occur here. The second part of the duodenum points vertically downwards curving over the head of the pancreas to reach the third part which proceeds to the left to its continuity with the jejunum.

Filling defects

Filling defects of the duodenal cap may be, as anywhere else in the gastro-intestinal tract, the result of extrinsic or intrinsic causes.

Very often a crescentic filling defect is seen on the cap or pyloric portion of the stomach, due to pressure of the gall bladder. Often owing to deficient tone the duodenal cap is enlarged and on emptying two pouches at the base remain filled with the opaque material.

Duodenal ulcer

The only really direct sign of a duodenal ulcer consists of visualizing the ulcer niche or crater.

Many indirect signs are of considerable value, such as:—

(1) Cicatricial contraction causing either by itself or by associated spasm a contraction in the centre of the cap, sometimes known as a 'kinuta' or mallet-like contraction.

(2) 'Fleeting' filling of the duodenum together with other signs of irritability.

Case 11.—Double penetrating ulcer at the base of the cap.

(3) Hyper-secretion.

(4) Pyloro-spasm, unaccounted for otherwise.

(5) Tenderness over the cap.

(6) Residues in the stomach at five hours.

As in the stomach, many types of ulcer are seen in the duodenum ranging from the flat type of superficial ulceration following duodenitis to deep penetrating ulcers.

Duodenitis

In this very common condition, often pre-ulcerative, a coarse reticulation is seen in the mucosal pattern, often associated with spasm. In many cases the cap appears contracted owing to engorgement of the mucous membrane. Tenderness is usually present. In many cases a bubble of gas is seen at the apex of the cap in cases of duodenitis and duodenal ulcer. Wilkie and others have pointed out what is now a commonplace, viz, the very constant association of duodenitis with chronic appendicitis and cholecystitis.

THE OPIUM SMOKING HABIT IN INDIA

PART I. GENERAL SURVEY

By R. N. CHOPRA, C.I.E., M.A., M.D., S.C.D. (Cantab.),
M.R.C.P. (Lond.)

BREVET-COLONEL, I.M.S.

Honorary Physician to the King
and

G. S. CHOPRA, M.B., B.S.

(Department of Pharmacology, School of Tropical
Medicine, Calcutta)**Historical and general*

THERE is little doubt that the medicinal properties of opium were known from very early times and that its euphoric uses were discovered later. The employment of this drug

* This work was commenced under a grant from the Indian Research Fund Association and during the last year has been carried on under the Endowment Fund of the Calcutta School of Tropical Medicine.

(Continued from previous page)

Diverticulum of the duodenum

This when present usually occurs in the second part. It is very rarely found in the first part and occasionally in the third. These sacs are not merely a herniation of the mucosa through weak spots in the musculature. They are probably true congenital sacs and are covered by all the muscle coats of the duodenum.

In the second part of the duodenum, diverticula usually retain their meal for long periods—often for twenty-four hours or longer.

Gastro-jejunostomy appearances

All cases of gastro-jejunostomy should be examined as soon after operation as they are able to get about, in order to ascertain the efficiency or otherwise of the operation.

It will be found in the vast majority of cases that the patient has not changed his habits and that as much meal as a rule will take the old route as the new unless something has been done to obliterate the old canal. Usually in three weeks or so, valvular action will have been established at the stoma.

Jejunal ulcer

In 2 per cent of cases of gastro-jejunostomy, jejunal ulcer occurs, usually within nine months of operation. Pain is felt soon after meals, rather lower down than in peptic ulcer and as a rule more to the left.

Sometimes an ulcer crater can be demonstrated by x-ray examination, more often not. The disturbance of the normal relationships, together with post-operative adhesions, makes diagnosis in these cases very difficult. Indirect signs of value are:—

- (1) Spasm and closure of the stoma.
- (2) Hyper-secretion.
- (3) Persistent irregularity about the stoma.
- (4) Tenderness.
- (5) Persistent stomach residues.

The method of mucosal examination by controlled pressure is of the greatest importance here.

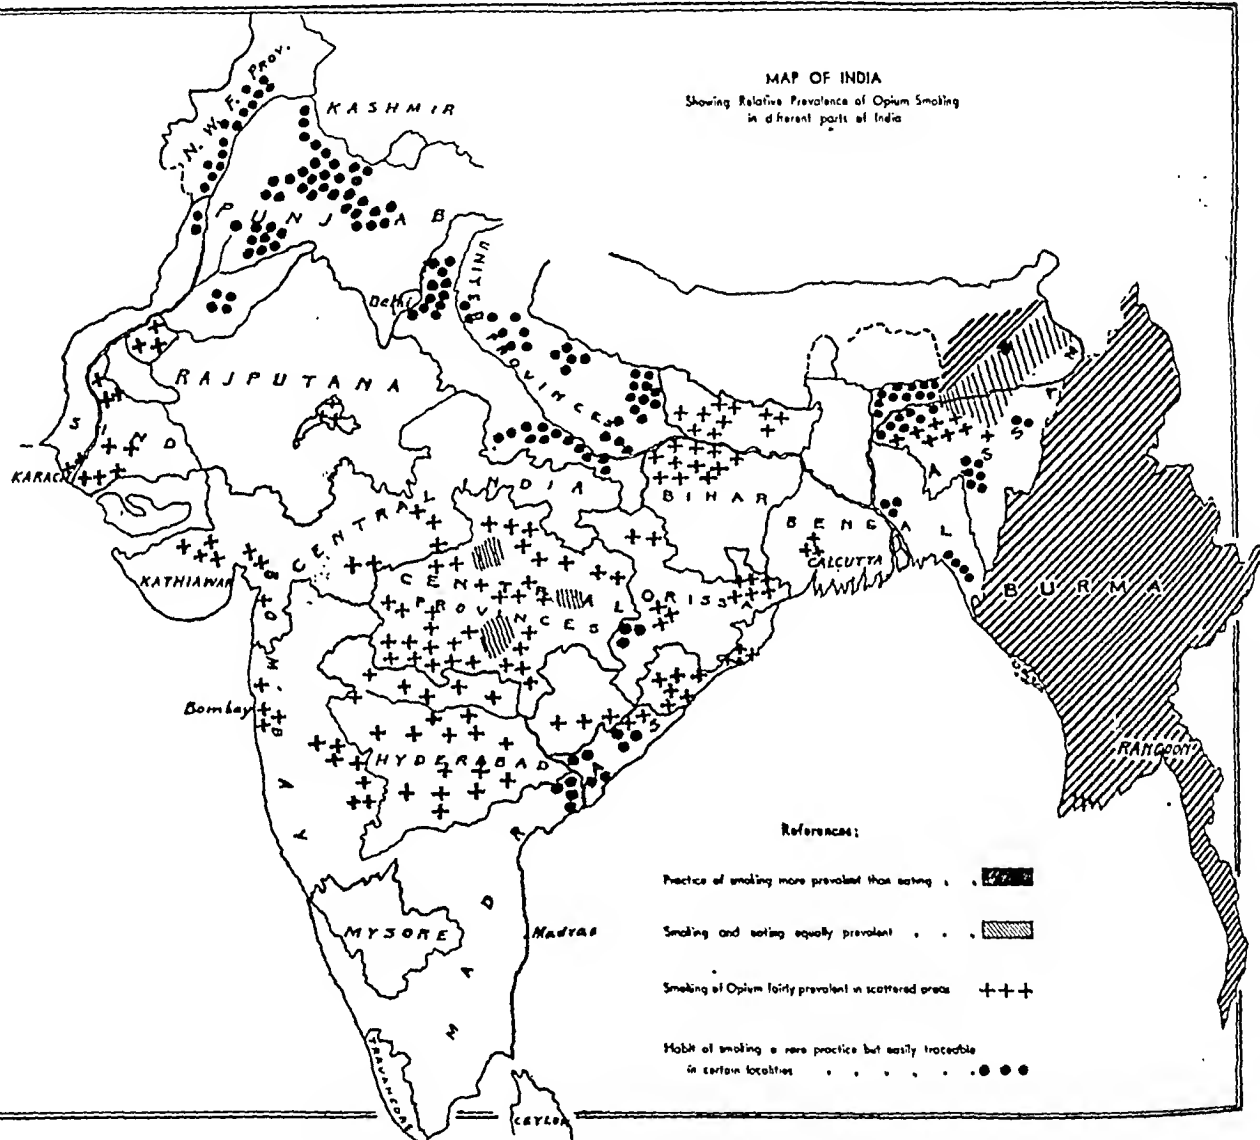

for its pleasure-giving effects spread very rapidly after their discovery and became so extensive in the East that prohibitory edicts and enactments were promulgated by rulers to prevent the spread of the habit. In spite of this, opium claimed more and more devotees. The drug was at first taken only by the mouth, but later, after the introduction of tobacco, it was smoked. Tobacco smoking is said to have been started in Asia first in the Philippine Islands by the Spaniards and from there it spread to China in the beginning of the seventeenth century. It would appear that in the early days of tobacco smoking various substances were mixed with it either to counteract its unpleasant effects or to strengthen the pleasant ones. Arsenic was one of these substances and opium was another.

The earliest record of the use of opium for smoking purposes is by Kampfer who in the end of the seventeenth century saw the inhabitants of Java offering for sale tobacco soaked in a solution of opium in water. In A.D. 1726 Francois Valentyn, a Dutchman, described the presence of 'modak' smokers among them. With the Dutch conquest of Formosa, the custom spread to that island and also to China. By the beginning of the eighteenth century, the habit had become so widespread that the authorities in the latter country were greatly alarmed regarding the evil effects which were being produced by it. In 1729 the first anti-opium edict was published by the then Emperor. In a Chinese work published in A.D. 1746 and translated by Dr. Edkins, opium smoking is described as follows: 'Opium for smoking is prepared by mixing hemp and grass cloth plant and cutting them into small pieces. This is then boiled in water with tobacco and smoked. This was the method in which it was smoked in these countries and China before the eighteenth century'. In 1796, the import was officially forbidden and opium smoking was made an offence punishable by death.

The Persians took to eating of opium early but there is no mention of opium smoking among them in the records of 'Kampfer's Travels', nor in those of Tavernier's (1657-70), though both describe eating and the smoking of 'hashish'. It appears to have been introduced later, probably after the Portuguese brought tobacco to the Persian Gulf in the early part of the seventeenth century. The Persians then became great smokers of tobacco and learned to grow tobacco themselves and invented the water-pipe (qaliam). They, however, never used the water-pipe for smoking opium though 'hashish' mixed with tobacco was occasionally smoked in it. Persians themselves admit that smoking of opium was unknown in their country until the nineteenth century and mention that the practice among them is not more than 110 years old. Other authorities assert that it did not begin there till after 1850. All agree that opium smoking was begun in

Khorassan, the north-eastern province of which Meshed is the capital. Here the famous shrine of Imam Reza is situated and here are attracted thousands of Shiah Mohammedan pilgrims from all parts of the world every year. It is a fair assumption, therefore, that opium smoking was first brought into Persia by pilgrims to Meshed. Certain it is that the Khorassanis are to-day more addicted to it than the people of any other province in Persia.

by the mouth for its euphoric effects in the times of Akbar is shown by the reference made to it by Abul-fazl in his book called 'Ain-i-akbari'. The testimony of European travellers shows that in the sixteenth century indulgence in this drug attained a considerable magnitude in many parts of India. It was mostly eaten at that time as no mention of opium smoking is made. Even up to the beginning of the nineteenth century no writer has recorded the

It is worthy of note here that before the Great War large quantities of morphine were sent to China in the form of packages of a proprietary cure for the opium smoking habit; a cure it might have been but it produced another vice infinitely worse. Opium smoking was in vogue in some parts of the United States where it was undoubtedly introduced through the agency of the Chinese immigrants.

Introduction of opium smoking habit in India

Opium, in all probability, was introduced into India by the nomadic Arab traders and invaders. That the drug was extensively taken

smoking of opium in India, although it prevailed in China. Exactly when the preparations made for smoking were first introduced and the habit of smoking opium first obtained a foothold in India is not quite clear. Fortunately, it never assumed such a menacing aspect as it did in China. The Royal Opium Commission of 1894 described the habit as 'comparatively rare and novel' in India.

A careful consideration of the available data points to the possibility of introduction of opium smoking in India by Mohammedan traders from Persia and Afghanistan. The stimulating and the narcotic properties of the drug combined

with the wonderful flow of ideas which occur early in the act of smoking, appealed to the easy-going, well-to-do section of society and the habit spread among them, particularly during the days of decline of the Moghul Empire.

Present extent of opium smoking in India

The habit of smoking opium is considered so disreputable that no self-respecting person will own to it. Besides this, there are restrictions placed on it by law, and both these factors make an accurate survey of its incidence very difficult. We have, however, by our work in the field obtained some idea with regard to its prevalence in different parts of India. In this work we have received the greatest help from ex-cise officers in all provinces. It is only these officers and the vendors who really know the persons who indulge in smoking, and it would have been impossible to form even an approximate idea of the prevalence of the habit without their active co-operation.

some of the old Hindustani books very detailed and somewhat exaggerated descriptions are to be found of this habit and the effects produced by it. Opium dens are found in many of the large towns in India even to the present day, but the proportion of people who smoke the drug is very small at the present time. Its incidence among the people is very irregular and, although there are areas and certain classes of the population which are badly affected, these fortunately form a very small minority.

Our enquiries show that the habit of smoking opium in one form or other is met with on a small scale in many of the large towns in India. The practice is at present confined to the poorer classes. A general survey of the incidence of the habit was carried out in different provinces and the results are briefly given in table I. It may be stated here at once that the habit of opium smoking has considerably decreased in India during the last 30 years. According to some authorities the reduction has been by as much as 75 per cent. Opium smoking, however,

TABLE I
Showing the total consumption of opium in different provinces in 1932-33, the approximate number of smokers and the localities affected

Provinces	Total consumption in lb.	Approximate number of addicts	Localities where the habit is reported to be still in vogue to an appreciable degree.
Madras	59,782	5,000 to 6,000	Ganjam, Vizagapatam, East Godavari and West Godavari districts and Madras town.
Bombay	38,084	900 to 1,000	Bombay, Ahmedabad, Poona, Sholapore, Broach, Ahmednagar, Surat, Nasik Thana.
Sindh	8,216	2,000 to 4,000	Hyderabad, Sukker, Mirpur Khas, Shikarpore and Jacobabad and Karachi.
Bengal	56,180	6,000 to 7,000	Calcutta and suburbs, Murshidabad, Dacca, Chittagong, Barisal and Darjeeling districts.
United Provinces ..	39,978	2,100 to 3,000	Shaharanpur, Bulandshahr, Muttra, Bareilly, Aligarh, Benares, Cawnpore, Agra, Fatehpur, Allahabad, Farrukhabad, Etawah and Gorakhpore districts.
Punjab	63,082	800 to 900	Lahore, Multan, Gujranwala, Jullunder, Rawalpindi, Ambala, Ferozepore, Ludhiana, Amritsar and Sialkot districts.
Burma	43,625	3,000 to 4,000	All over the province particularly in Northern and Southern Shan States and in all towns and Arrakan areas.
Bihar	38,493	6,000 to 8,000	Shahabad, Saran, Champaran, Muzaffarpore, Bhagalpore, and Singhbhum districts.
Orissa	2,000 to 3,000	Orissa province as a whole and towns like Cuttack and Puri.
Central Provinces ..	25,388	12,000 to 15,000	Narsingpur subdivision, Nagpur, Ellichpur, Balaghat, Jubbulpore, Akola, Amraoti, Buldana, Yeotmal, Wardha, Rajpur, Bilaspur and Mandla districts.
Assam	26,765	20,000 to 25,000	Hill tracts particularly Sadiya frontier tracts, Makir hills of Nowgong and Sibsagar districts.
North-West Frontier Province.	1,682	3,000 to 5,000	Towns like Peshawar, Kohat, Hoti Mardan, Dera Ismail Khan and Bannu.
Administered areas (Baluchistan, Ajmer-Merwara, Coorg and Delhi).	10,922	200 to 400	Delhi and Ajmer towns.

A study of the records leaves little room for doubt that opium smoking has always been an uncommon practice in India. That it did exist and does exist even now among certain classes is evident from the fact that the word 'chandu-baz' or opium smoker is well known and in

appears still to be practised in many of the large towns among the lower strata of the society.

In the following pages we give the information we have gathered with regard to its prevalence in different parts of India.

Opium smoking in Assam

During the latter part of the seventeenth century, when the Moghuls came in contact with the kings of Assam, it is probable that some time or other opium or 'affing' as it was called was sent as a present to the Assam (Ahom) kings. It would appear that from about this time the habit of eating opium was introduced into Assam. Neither the available literature nor the local chronicles, which describe the details of the royal functions and the events of each day before the eighteenth century, have any references either to poppy cultivation or habitual use of opium among the people of Assam. That the royal court indulged freely in the drug by the end of the eighteenth century, can be gathered conclusively from the report of Captain Welsh in 1792 to Lord Cornwallis. He describes the King Gaurinath Singha, as 'a poor debilitated man, incapable of transacting business, always either washing or praying and, whenever seen, intoxicated with opium'. Again, in Captain Welsh's report we read further, that he required 'a few boat loads of opium for sale because it was useful for the purchase of rice, etc., for the troops'. It is not exactly known when the drug was first introduced into the Assam valley but it is certain that poppy was widely cultivated there in 1773, and its use became so extensive in the nineteenth century that measures had to be taken to prevent its abuse. It was observed by one of the writers of that period that three-fourths of the population were habituated to opium.

There appears to be little doubt that the habit of smoking opium was introduced into the valley by clandestine methods from the north. In Assam the inhabitants, for some reason, gave themselves up completely to the drug and opium smokers have always formed a considerable portion of the indigenous population of Assam. The Kacharis were so passionately addicted to it that they sometimes demanded to be paid in opium instead of money. Both men and women among the Kakhyens, Karens and Lpais, the inhabitants of the Khasi mountains, smoked opium. They could produce only very small quantities of the drug on account of the high altitude in the mountains, but they obtained large quantities from China. The wild tribes of Turungs and Nagas descended from their hills into the valleys in order to barter ivory, for rice and opium. Certain tribes of the adjacent parts of Burma, the Parjii and the Kachion, are badly addicted to this habit.

Opium smoking is said to have increased in Assam after the prohibition of poppy cultivation in 1860. Some of the old addicts whose memory goes back to that period state that only about 5 per cent of the consumers were smokers at that time. Probably the form in which opium was then commonly manufactured was not suitable for smoking purposes. The habit later spread rapidly and practically every opium addict preferred to smoke it if he could

afford to do so. Amongst those who took to opium for its pleasure-giving effects and many of those who used it to control the symptoms of diseases and ailments, smoking of opium was universal. Almost every one smoked opium in the first instance and only took to other modes of consumption after he had become a confirmed smoker and found that he could afford neither the time nor the money required for smoking.

It is difficult to form an accurate estimate of the relative proportions at any one time of those who smoke opium and those who take it by the mouth. The economic condition of the consumer appears to be an important factor in this connection. When times are good and money is easy to obtain, the stage at which smoking is given up and the less expensive form of indulgence, i.e., eating is taken up, is postponed. When times are hard this is done quickly. Similarly, the poorer classes have to give up smoking earlier than those who are well off. According to the estimate we have formed by our work in the field, the proportion of opium smokers to opium eaters in the province of Assam as a whole at the present time is one-fourth and not one-half or one-third of the total opium habitués, as the Botham Committee (1912) and Assam Congress Inquiry Committee (1925) respectively reported. In some places figures may be higher. In Lakhimpur Sadiya frontier tract, for instance, we found that the proportion of smokers to eaters was 4 to 11 in several localities, but this is not the case in other parts of Assam. The reason why the proportion of smokers is put down to be high by some people is partly because the evils of smoking bulk large in their view, and partly because they are apt to confuse the number of those who

TABLE II

Showing incidence per 10,000 population and also total consumption in pounds in various districts of Assam during the year 1932-33.

District	Consumption in lb. during the year 1932-33	Incidence per 10,000 of population in lb.
Kamrup	1,740	17.8
Goalpara	58	0.64
Cachar	852	14.8
Sylhet	124	0.44
Khasi and Jaintia hills ..	694	23.8
Naga hills	448	25.0
Balipara frontier tract ..	38	63.8
Darrang	2,676	44.0
Nowgong including Mikir hills.	3,052	54.0
Sibsagar including Mikir hills.	8,548	90.0
Lakhimpur	5,084	124.0
Sadiya frontier tract ..	1,008	188.0
Whole province	28,448	30.6

have been smokers in the past with the number who are smokers at the present time. From our inquiries in different tea estates it would appear that the proportion of smokers is much the same here among the imported labour as amongst the indigenous population.

The present position of opium smoking in Assam

It will be seen that, with the exception of Sylhet and Goalpara, all other districts show a rise of the curve above the standard laid-down by the League of Nations. The consumption is high in the upper districts of Assam valley, particularly in the hill tracts and the Sadiya frontier tract. The consumption of opium here ranges between 122 to 188 lb. per 10,000 of population and the opium conference at Simla in 1930 marked these as 'black spots' in the province. This unusually high consumption is due to smoking of opium, which necessitates a much larger dosage of opium per head than taking it by the mouth. We have observed that opium smoking is commoner among the hill tribes. In the plains much less opium is consumed, the consumption being the highest in Lakhimpur district (124 lb. per 10,000 population per annum) and lowest as one goes southwards, i.e., in Nowgong district (34 lb. per 10,000 persons

average consumption per month per individual is 270 grains.

In table III we have given the comparative figures of consumption of opium in the hill and plain areas of two districts in which the incidence of the opium habit is high. Sibsagar and Nowgong districts adjoin each other and have a common hilly tract called Mikir hills and the inhabitants of this area are particularly fond of opium smoking.

This table is of special interest inasmuch as it shows that the incidence of addiction to opium in the hill areas is almost five times that in the plains; for example, it is 172 lb. in the Sibsagar Mikir hills as compared to 34 lb. per 10,000 in the plains of the same district. There are proportionately more habitués in the hill areas, the proportion to total population being 1 in 19 and 1 in 34 in the hill areas of the two districts respectively as compared with 1 in 71 and 1 in 52 in the plains of the same district. Further, it will be seen that the average monthly allowance of each district is practically the same in the two areas, indicating that the mode of consumption is probably the same, i.e., smoking.

To sum up briefly, the consumption of total excise opium in the whole of Assam including Manipur State was 26,765 lb. during 1932-33.

TABLE III

Showing difference in consumption and the number of consumers on the register in plain and hill areas of Sibsagar and Nowgong districts in 1932-33

		Total consump- tion in lb.	Incidence per 10,000 population according to census of 1931	Average monthly consump- tion per individual in grains	Number of consumers on the register	Percentage of pass holders to general population	Total population according to census of 1931
Plain areas							
Nowgong district	1,702	34	145.8	6,950	1 in 71	484,831
Sibsagar district	7,866	88	270.0	17,399	1 in 52	877,960
Hill areas							
Nowgong district	1,350	172	198.0	4,016	1 in 19	77,750
Sibsagar district	682	122	212.0	1,628	1 in 34	55,466

per annum). The districts of Sylhet and Goalpara have a consumption even lower than the League standard, being 0.44 and 0.64 lb. per 10,000 per annum. The consumption is high in Khasi and Jaintia hills and Balipara frontier tract where it reaches 73.8 lb. per 10,000. The comparatively high consumption rate in Cachar is due to the fact that Northern Cachar hills are malarious and the labourers employed there in the timber industry smoke the drug under the belief that it has a prophylactic value. Out of the total population of 32,844 there were 1,338 pass holders (4 per cent of the population); this works out to be 1 in 25 of the population. The

The total population of the province according to the last census report was 9,247,857 and the incidence of opium consumption per 10,000 of population per annum works out to be 30.6 lb. per annum as compared with 84 lb. in the 'black spot' area and 29.4 lb. in plain areas and 38 lb. in the Mikir hills, North Cachar hills, frontier tract of Sadiya and Balipara, and Manipur State. The addiction is uncommon in Lushai and Garo hills. In Manipur State the incidence is very low, i.e., only 2.8 lb. per 10,000 of population per annum.

Number of consumers in the province.—The number of registered opium addicts in various

districts of the province and the average daily dose are shown in table IV.

TABLE IV

Showing the number of registered opium addicts in various districts in Assam province during the year 1932-33 and average daily dose

Districts	Number of registered addicts	Proportion of the registered pass holders to general population	Average daily dose in grains
<i>'Black spot' areas</i>			
Darrang ..	7,602	1 in 77	7.02
Nowgong ..	10,966	1 in 51	5.52
Sibsagar ..	19,027	1 in 49	8.94
Lakhimpur ..	20,414	1 in 35	8.58
Sadiya frontier tract.	1,665	1 in 32	12.06
TOTAL ..	59,674	1 in 48	7.96
<i>Other areas</i>			
Kamrup ..	4,576	1 in 213	7.2
Goalpara ..	153	1 in 5,769	7.2
Cachar ..	2,085	1 in 273	7.8
Sylhet ..	411	1 in 6,628	6.0
Khasi and Jaintia hills.	1,765	1 in 164	7.8
Naga hills ..	671	1 in 266	13.2
Balipara frontier tract.	56	1 in 91	13.2
TOTAL ..	69,391	1 in 126	6.8

As regards the actual number of opium addicts in these areas, the survey we have made leads us to believe that the actual figures on the official register do not represent the true number of addicts and that there are at least half as many more addicts who still remain unregistered and consume the drug obtained from various illicit sources. As regards the proportion of pass holders to general population they form the smallest percentage of population in Darrang—1.29 per cent. The number is very high in the Mikir hills of Nowgong district where they form 5.1 per cent. Taking the whole population in the province, excluding Manipur State, there is one pass holder for every 126 persons as compared with 1 in 48 in the case of 'black spot' areas. According to the estimate we have formed there would approximately be between 20,000 to 25,000 smokers in this province.

Average daily dose.—A perusal of table IV will show that the average daily consumption per pass holder is highest in Sadiya frontier tract, being 12.06 grains a day, and is the lowest in the Nowgong plain areas where it is 4.86 grains a day. For the 'black spot' areas as a whole the average dose per registered addict works out to be 2,700 grains a year, 225 grains a

month, or 7.86 grains a day as compared with 6.8 grains per day of other areas.

Decline of opium smoking in Assam.—Our enquiries show that the habit of smoking opium has declined considerably in Assam during the past 20 years, and this is borne out by the fact that the consumption of the drug per 10,000 of population per annum has been greatly reduced during this period. This is specially the case with the 'black spot' areas.

TABLE V

Showing opium consumption per 10,000 population in 'black spot' areas of Assam province in pounds during the years 1920-21, 1927-28 and 1932-33

'Black spot' areas	CONSUMPTION IN LB. PER 10,000 OF POPULATION		
	1920-21	1927-28	1932-33
1. Darrang ..	344	118	44
2. Nowgong with Mikir hills.	582	240	54
3. Sibsaagar with Mikir hills.	336	180	90
4. Lakhimpur ..	610	284	124
5. Sadiya frontier tract ..	458	206	188
6. 'Black spot' areas as a whole.	458	206	84
Province as a whole ..	161.6	72.2	30.6

The reduction in opium consumption during the past 16 years is undoubtedly the result of registration of addicts, the reduction in number and rationing of shops, the enforcement of the Opium Smoking Act, and also the 10 per cent reduction in the annual ration of each addict. It appears that the consumption of opium was rather alarming during the year 1920-21, before the restrictive measures were adopted. As a result of these measures the habit of smoking opium, in many localities, has been replaced by that of eating which is satisfied by smaller quantities of the drug. In 1920-21 the consumption of the drug in 'black spot' areas was 458 lb. per 10,000 of population, in 1927-28 it fell to 206 lb. while in 1932-33 it dropped to 84 lb. only. Not only do the 'black spot' areas show marked decrease but the incidence in the whole province also has fallen simultaneously from 161.6 lb. per 10,000 population during 1920-21 to 72.2 lb. (by 55 per cent) in 1927-28 and it has further dropped in 1932-33 to 30.6 lb. Taking the province as a whole the consumption of the drug has fallen from 129,190 lb. during the year 1920-21 to 57,766 lb. during the year 1927-28 and to 28,448 lb. during 1932-33. Thus the present consumption has come down to even less than one-fourth of what it used to be 16 years ago. This wide range in variation can be duly explained by the fact that most of the smokers have now taken to opium eating.

The actual number of the registered consumers does not show corresponding decrease. There were 85,976 registered addicts during the year 1927-28 and 69,605 during 1932-33. This reduction does not correspond with the fall of total consumption of the drug for reasons already explained. Further, it may be observed that the average daily dose showed a reduction from 13.2 to 6.8 grains. This is due to the fact that the opium smoking habit is gradually being replaced by eating.

Opium smoking in the Central Provinces

We have carried out a detailed survey of the prevalence of this habit in this province during the last few years and find that its incidence is still high as compared with some of the other provinces of India. It is not exactly known when the habit was introduced into this province. The Opium Inquiry Committee (1929) reported that 'the opinion is pretty generally expressed that the habit, especially that of "madak" smoking, began among the Mohammedans and this fits in with the fact that at present the habit is most prevalent in that community and with the high consumption in Ellichpur, which is largely a Mohammedan town'. The cultivation of poppy was started in this province about 200 years ago and the information available goes to show that smoking was introduced nearly a hundred years later. It would appear that the habit of smoking was first contracted by a few rich landowners of the province from their retainers, who were generally Mohammedans from outside. It proved enjoyable in company, began to acquire a social value and at one time it was common for a smoke of opium to be offered to guests and visitors as a mark of hospitality. Moreover, opium was very cheap in former days and was easily obtainable anywhere. 'Madak' smoking thus spread extensively in some localities where the idle rich class of landholders resided. In the districts of Berar it is quite likely that the habit was originally introduced by the Mohammedan rulers who hailed from Persia. This legacy has thus been handed down to the people and opium smoking was indulged in in spite of restrictions that were later introduced. The Opium Smoking Act has been in full force since 1932; according to this Act smoking is an offence. It has, however, not been possible in practice to suppress the offence entirely. The excise authorities have been able to check smoking in assemblies, but the individual smoking of the drug in secret still continues and is difficult to detect. The opium law in the province was further strengthened in the year 1934 by making it unlawful for any person to smoke opium and to possess a pipe or any other apparatus for smoking or preparing opium for smoking purposes. It would appear from the study of table I that the total consumption of opium during 1932-33 was 25,388 lb. and the number of smokers on

official record was 10,345, a figure probably somewhat on the low side.

'Madak' is the preparation which was principally used for smoking in this province. The types of persons given to opium smoking are low-class Mohammedans, artisans, hackney carriage drivers, and a few agriculturists. It is a vice of the urban rather than of the rural areas. The incidence is high in Narshingpur subdivision and the habit is also fairly prevalent in the adjoining areas of Hoshangabad and Jubbulpore districts. There are also a large number of habitués amongst the Mohammedan population of Elliehpur, Balaghat, and Jubbulpore towns. In certain areas of Akola, Amraoti, Buldhanha, Yeotmal and Wardha districts, the habit also exists in the lower strata of society. Opium smoking has also spread to certain districts inhabited by the aboriginal tribes—Raipur, Balaghat, Bilaspur, and Mandla. The departmental estimate of 'madak' smokers in these districts in 1933 was 1,707, 868, 490 and 400 respectively. Raipur was worse even than the notorious Narshingpur subdivision in which the number was 1,500.

*Opium smoking in Burma**

It is not exactly known when opium was first introduced into Burma. Cæsar Fredericks, a Venetian, who travelled in the East for eighteen years, described at some length in A.D. 1591 his two ventures in importing opium into Burma from Cambay and the port of Chawl on the West Coast of India. F. C. Danvers of the Dutch East Indies Company, in a memorandum from the Hague, refers to the Company's trade in opium in the year A.D. 1613. It is mentioned that at that time 200 lb. of opium were annually sold in the Malaccas and that the drug was profitably sold in Siam and Pegu. Opium was thus in use in Burma over three hundred years ago.

In Burma, as in China, the smoking of an extract of pure opium is of comparatively recent origin. The annexation of Arracan by Bengal after the first Burmese war led to an increased consumption of opium by the Arracanese as the regulation for the sale of opium in Bengal was not at that time stringent. In the first Burmese war, after the stockade at Kemmendine was captured, a quantity of raw opium was discovered. Even to-day by far the largest number of consumers are to be found in Arracan.

In Burma besides the special opium pipe, prepared opium is smoked in the form of what is known as 'katpon'. It is made by mixing the prepared opium with dried plantain-leaf torn into shreds and dried over a fire, the opium being thoroughly mixed with the leaf. This is then smoked in an ordinary pipe.

On account of the large Chinese population, the smoking of opium is very prevalent in

* When this survey was done Burma was a part of India.

Burma. Among the Burman addicts, more eaters of opium than smokers have been registered. The import into Burma of opium prepared for smoking is prohibited, but its manufacture and use are allowed, subject to certain restrictions. In order to discourage smoking the manufacture and sale of prepared opium were discontinued in the licensed shops from the 1st April, 1921. Those who desire to smoke opium now have to prepare it themselves. In 1924 a law was made prohibiting any person other than a registered smoker from possessing prepared opium, and a register for opium smokers was opened for six months from 9th January, 1924. Up to 31st March, 1932, no new names could be added to the register and it was expected that with the gradual disappearance of the persons registered in 1924, opium smoking would cease to be permitted in Burma, except in a few of the backward tracts. In 1929 a Commission of Enquiry into the Control of Opium Smoking was appointed by the Council of the League of Nations which visited Burma and the countries in the Far East. This Commission condemned the system of a closed register on the ground that this did not lead to a suppression of the opium habit but drove the consumers to the use of illicit opium. This and other recommendations were examined by a small committee composed mainly of members of the Burma Legislative Council. The committee after due consideration recommended that the Government of Burma should adopt the ultimate suppression of opium consumption among all races in Burma as the goal of its policy and that in order to achieve this end the system of a closed register should be abolished. As a result of this recommendation the opium smokers' registers which had been closed since 1924 were thrown open with effect from the 1st April, 1932. The total number of registered smokers of opium by the end of 1933 was 20,678. About 67 per cent of these registered smokers were Chinese and Burmese, with only a very small proportion of Indians and others.

Since the reopening of the register of Burman opium addicts, both eaters and smokers are coming forward to get themselves registered. Of 43,623 lb. of opium consumed during the year 1932-33 approximately 26,587 lb. were consumed by registered smokers and 17,036 lb. by the eaters. The Government of Burma had under consideration a proposal to license smoking saloons with a view to providing reasonable facilities for smoking where such may be necessary and at the same time enabling the excise staff to take effective action against unlicensed saloons.

The present extent of opium smoking in Burma

There were 53,000 licensed opium eaters, and smokers in Burma, out of a population of 14,667,146 in 1933. The number of illicit opium consumers is, probably quite large in view of the fact that 6.15 per cent

of the convict population are, as far as can be ascertained, unlicensed opium consumers. Licit and illicit traffic have been aptly likened to 'two streams, one open to the day on the surface and the other hidden underground, both closely connected and both running more or less in the same general direction'. It has been estimated that approximately 7 per cent of the non-European population of Burma consume opium in one form or another. The incidence of opium addiction runs parallel to the population density and the opium trade routes, thus it is more common in large urban centres such as Rangoon and Mandalay and the frontier districts. In the deltaic areas of Burma and Arracan, where two-thirds of the opium consumers in Burma reside, the drug is consumed in small doses as a prophylactic against disease. As regards the use of opium as a stimulant, the practice of taking the drugs is old-standing, is indulged in in moderation, and is believed to produce no injurious effects. Burman consumers are as a rule mostly eaters. In the year 1932-33 out of a total of 16,000 registered consumers only 4,000 were registered as smokers. With Chinamen it is different and out of a total of 13,813 registered consumers 12,720 were registered smokers. Recent figures (March 1936) show the number of registered smokers at 17,388, of which approximately 68 per cent are Chinese, 20 per cent Burman and 2 per cent Indian. This total does not include the whole province as the smokers in frontier districts are not registered. Whereas amongst the Chinese opium consumption is to be found in all grades of society, in the case of other nationalities it is practically entirely confined to the lower strata of society.

Opium consumption in Burma appears to be specially confined to the male sex, excepting perhaps in the Kachin hills and the Shan States where female addicts are not uncommon. This is indeed fortunate, as established addiction among women is notoriously difficult to cure.

Opium smoking in other parts of India

Madras Presidency.—Our enquiries show that opium smoking is still met with in the Agency Tracts of Ganjam, Vizagapatam and East Godavari districts. In the city of Madras a few opium smoking dens are said to exist. The habit has, however, almost disappeared from the southern part of the presidency. The number of addicts cannot be more than five to six thousand in the whole of this province.

Bihar.—The habit of smoking 'madak' prevails to a certain extent in some districts but is usually confined to towns and important centres of trade. There were 5,979 individual registered smokers under the 'Bihar and Orissa Opium Smoking Act' up to 31st December, 1931, when the register was finally closed. There are probably 4,000 to 5,000 opium smokers in this province at the present time. 'Chandu' smoking is met with to a limited extent in certain urban areas in the districts of Shahabad,

Saran, Champaran, Muzaffarpore, Bhagalpore and Singhbhum.

Orissa.—The habit of smoking 'madak' is encountered in some of the towns and centres of trade. The number of persons registered under the Bihar and Orissa Opium Smoking Act up to 31st December, 1931, when the register was finally closed, was 1,902. It is probable that an equal number were left unregistered. 'Chandu' smoking is practised to a limited extent in certain urban areas in the districts of Cuttack and Puri.

United Provinces.—According to the reports of district officers in 1935, smoking of opium is practised in 19 districts of the United Provinces and 107 persons were convicted under the Opium Smoking Act. The principal towns where the habit is met with are Saharanpur, Bulandshahr, Aligarh, Muttra, Agra, Bareilly, Farrukhabad, Etawah, Cawnpore, Fatehpur, Allahabad, Benares and Gorakhpur. The Opium Smoking Act of 1934 came into force on 1st August, 1935, and provided for registration by habitual opium smokers within a specified period. No person below the age of 25 can get himself registered. The period up to which registration was possible expired on 31st December, 1936. The approximate number of smokers in the whole of the United Provinces, as reported by the district officers, is 2,777. This figure is on the low side as there is no information regarding the unregistered smokers.

The Punjab.—The habit of smoking 'madak' and 'chandu' is met with to a limited extent in most of the district towns all over the province. It was possible to trace smokers in Lahore, Multan, Gujranwala, Jullunder, Rawalpindi, Anbala, Ferozepore, Ludhiana, Amritsar and Sialkot districts though in small numbers in each city. The probable estimate of the number of smokers for whole of the province is 800 and 900.

North-West Frontier Province.—'Chandu' is usually smoked here and the habit although not common is met with in towns like Peshawar, Kohat, Hotimardan, Dera Ismail Khan, and Bannu. The probable number of smokers in this province is not more than 500 to 1,000.

Ajmer Merwara.—A number of opium smoking dens existed in Ajmer town and the estimated number of smokers would probably not be more than 50, chiefly among the mendicant class.

Bengal Presidency.—Smoking of opium is common amongst the Chinese population in Calcutta and its suburbs and it is estimated that 40 per cent of them smoke opium. The habit can also be traced amongst the labourers and mill hands in the suburbs of Calcutta. In smaller towns like Murshidabad, Dacca, and Mymensingh the number of smokers is negligible. The approximate number of smokers in the presidency would probably not be more

than 6,000 to 7,000. The Tibetans, Assamese and Mughls in the districts of Darjeeling and Chittagong rarely smoke opium. The Opium Smoking Act and the rules made thereunder had the desired effect throughout the presidency and the number of smokers has gradually declined, but supplies of prepared opium are sometimes obtained from illicit sources. No prepared opium is allowed to be sold.

Bombay Presidency.—The habit of smoking both 'madak' and 'chandu' is common among the Chinese and Persian population in Bombay city itself and it is also encountered amongst the low-class Mohammedans and mendicants. In the town of Bombay alone there are about 500 opium smokers out of which 300 are Chinese and Persians. In the following towns in the presidency a few smokers probably exist but the habit is gradually dying out: Ahmedabad, Poona, Sholapur, Broach, Ahmednagar, Thana, Nasik and Surat. The approximate number of opium smokers in this presidency is between 900 and 1,000.

Sindh.—The practice of smoking opium is met with in Karachi like other large sea-port towns of India. There were a number of smoking dens in this town which were mostly frequented by low-class Mohammedans, Chinese and Persians. Smoking is practised on a small scale in towns like Hyderabad, Sukkur, Mirpur Khas, Shikarpur and Jacobabad. There are approximately 2,000 to 5,000 opium smokers in this province.

Opium smoking and hemp drugs.—From the survey we have made we have formed the impression that opium smoking has greatly declined throughout India during the last few decades and is even more rapidly declining during recent years; this decline is due to the stringent measures taken by the excise authorities against it. In some of the areas we have found that its place is being taken by the less expensive and perhaps also less injurious habit of smoking of hemp drugs.

HYDATID DISEASE IN THE PUNJAB*

By M. A. SAMI, F.C.M.S., M.B.M.S. (Punjab)

Assistant Surgeon, Rajanpur,

D. G. Khan (Punjab)

THE object of this note is to draw attention to the relatively high incidence of hydatid disease in the south-western portion of the Punjab, a fact that has not been previously recognized. All the cases reported have come from a rural population of about 200,000 and they have all been seen in the last six years. The disease seems widespread throughout the area for at least one or two cases have come from practically every village in the district. It should also be noted that the records only include those patients who came to hospital, so it is probable the cases reported only represent a small proportion of the total number in the district. Another fact is that these observations were made at Rajanpur, which is only a small *tehsil* hospital, so that apart from the cases operated upon clinical findings only were available. It is therefore possible that other cases were missed that might have been found if more accurate methods of diagnosis had been available.

Case 1.—M., aged 30, male, sweeper. He noticed a small swelling eight years ago in the right hypochondrium. To this he paid no attention. It slowly grew bigger. During the last two months it had suddenly enlarged, with pain in the region, and he had fever. The lower half of the right side of chest in front and corresponding hypochondrium became oedematous, red, and tender; fluctuation present. He was emaciated, temperature 102°F., face flushed and moist, slight dry and painful cough, basal pleurisy. Operated on on 8th September, 1931, under chloroform; vertical incision two inches over the swelling which was found adherent to the parietal wall. Contents removed and cavity drained. Cavity occupied right lobe of liver. Contents consisted of very foul-smelling pus mixed with degenerating cyst wall and daughter cysts; progressed well; discharge dried up. Left the hospital against medical advice on 27th October and came back on 29th December, with infection in the cavity and lung abscess. Died on 2nd January, 1932, from exhaustion and toxæmia from abscess of the lung.

Case 2.—S., aged 20, female, housewife. She noticed a small swelling in the epigastrium a year ago. It slowly enlarged. This was movable up and down with respiration and was connected with the margin of the liver on left side; fluctuation present. Operated on under chloroform through paramedian incision. A cyst on the lower surface of the left lobe of the liver was found, and completely excised. Abdomen closed; recovery uninterrupted.

Case 3.—G. R., aged 35, male, agriculturist. He noticed swelling of abdomen some six years back, loss of appetite, occasional colic, not very severe. He was anæmic. Abdomen prominent, nodular, tense, seemed full of small swellings each about the size of a fist. Every one of them fluctuating. They were all movable. He was afraid of taking full meals on account of discomfort and tension induced. Some dry cough. Areas of dullness all over the chest on both sides. Operated on on 15th February, 1932, under chloroform to explore the condition in abdomen and relieve if possible its tension. Omental and mesenteric cysts were found, fifteen of which were removed. Liver and spleen were studded with similar cysts. Abdomen closed; quite well up to 8th March, when

he died of rupture of cyst in the peritonæum, as evidenced by immediate urticaria and later peritonitis.

Case 4.—T., aged 40, female, housewife. She noticed a swelling in the right hypochondriac region, movable, slightly painful, pain was increasing. Swelling was connected with liver, globular about the size of infant's head; fluctuation present. Operated on under chloroform through pararectal incision. A cyst was localized on the under surface of right lobe of liver. Contents evacuated, consisted of cyst wall and daughter cysts which were undergoing degeneration. Cyst wall anchored to the anterior abdominal wall and drained. She developed pneumonia after the operation, otherwise recovery was uninterrupted.

Case 5.—J., aged 56, female, beggar. She noticed a small swelling in the right upper part of abdomen some thirty years ago which had since enlarged. Now occupies the whole of abdomen except the left iliac fossa. Fluctuation is present, hydatid thrill present. In the upper part of the swelling an area of two inches is soft and at times reducible through a small hole. On straining and coughing the swelling recurs. She was operated on on 1st September, 1932; cyst was adherent to the abdominal wall. At its centre there was an opening which admitted the thumb, in the upper part of the linea semilunaris, under the skin communicating with the cyst. This formed the hernia. The contents of the cyst were removed through the incision. Contents consisted of 10 pints of cysts and daughter and grand-daughter cysts and fluid which were closely packed in the cavity. Cavity measured 12 inches in diameter. Recovery uninterrupted except for an attack of pneumonia. Ventral hernia at the site of incision.

Note.—Only the left lobe of liver and small portion of right lobe could be made out after operation, otherwise the whole liver was replaced by the cyst.

Case 6.—K. B., aged 30, male, agriculturist. He noticed a swelling in the right hypochondrium slowly growing bigger. There was no other complaint. For the last fifteen days he began to get fever and the swelling suddenly grew bigger and became painful. Pain constant and agonizing. Swelling occupying the right upper half of abdomen, tender, painful, and continuous with liver. Temperature 103°F. Operated on under chloroform on 23rd September, 1932. Cyst was found in the right lobe of the liver. Cyst wall was anchored to the abdominal wall. Cavity opened and drained. Contents consisted of very offensive pus and daughter cysts. Recovery uninterrupted.

Case 7.—C., aged 25, female, Mohammedan, agriculturist. She noticed a swelling two years ago in the middle of the forehead. This slowly enlarged to the size of a walnut. Skin healthy and movable over the cyst and cyst movable on the underlying tissue. Operated on on 12th February, 1933, under local anaesthesia and the cyst enucleated. Healed by primary union.

Case 8.—R., aged 27, male, Mohammedan. He noticed a painless swelling in the right hypochondrium four years ago. It gave him pain occasionally when he exerted himself. The swelling is continuous with the liver, movable with it and fluctuating. Operated on on 2nd March, 1933, under chloroform through a vertical incision over the cyst. The cyst wall was anchored to the abdominal wall and opened. The contents consisted of clear fluid with few growing daughter cysts. When shown to him after the operation he said that he coughed out similar material some two years back, with some blood. Recovery uninterrupted.

Note.—He had had a lung cyst causing no symptoms which healed spontaneously by rupture and expectoration.

Case 9.—M., aged 30, male, Mohammedan, agriculturist. He noticed two swellings, one in the right hypochondrium and the other on the right side of the umbilicus, six years ago. Both grew bigger as time passed. The upper swelling was continuous with liver and was the size of a closed fist, fluctuation present. The lower cyst seemed in the abdominal wall; it was fixed, nodular and fluctuation was slight. Operated on on 2nd March, 1933, under chloroform. No. 1

* Rearranged by the Editor.

through a vertical incision over the cyst. Cyst was in the right lobe of liver, anterior surface. No. 2 through a separate incision over the cyst. Cyst was found outside the peritoneum and behind the rectus sheath. No. 1 consisted of a single cyst, and no. 2 of numerous exogenous cysts. Recovery uninterrupted.

Case 10.—B., aged 25, female, Mohammedan, housewife. She noticed a small swelling in the right upper part of abdomen after her first delivery seven years ago. She did not pay much attention to it. She had another child three years ago. This time the swelling began to increase gradually. Twenty-one days before coming to the hospital it increased suddenly and painfully. The swelling occupied the right hypochondrium, part of the epigastric and right umbilical and lumbar regions. It seemed to be in the abdominal wall, fluctuation present, slightly tender, no fever. Operated on under chloroform through a vertical incision over the most dependent part and the cyst contents consisting of cyst wall, daughter cysts and turbid fluid drained. This cyst was exterior to the peritoneum. Recovery uninterrupted.

Case 11.—I., aged 25, female, housewife. Growth in the right upper outer part of abdomen, hard, fluctuating, the areola and partly outside it. Diagnosis of retention cyst made and operated on under local anaesthesia. Cyst removed and found to be a hydatid. Healed by primary union.

Case 12.—T. B., aged 30, Hindu, male, shopkeeper. He noticed a swelling in the right upper part of abdomen about five or six years ago. Swelling was gradually increasing and getting more painful. Pain came in attacks lasting one or two days, then an interval of quiescence of several days. These painful attacks were getting more frequent and keeping him away from work. He also sometimes complained of pain in the right shoulder. Pain had no relation to meals. The swelling occupied the right hypochondrium and part of the epigastric region, it was continuous with the liver and movable with it, painful on pressure, fluctuation present. He was anæmic and had slight fever ranging from 90° to 100°F. for the last two months. Operated on under chloroform through a vertical incision over the swelling below the costal margin. Cyst was found in the right lobe of liver and was anchored to the abdominal wall. Contents consisting of cyst wall, degenerating daughter cysts and turbid fluid were removed. Progressed well except for occasional attacks of malaria.

He began to get pain in the abdomen six months after he had left the hospital. The pain was colicky in nature and came on two or three times a day. One day it was very severe but it suddenly ceased and he passed blood and some cysts similar to those seen at the operation. The pain did not reappear for some time afterwards. A month later he began to get fever and the previous wound became painful and swollen. He came back to the hospital. The scar was raised over a fluid swelling which was opened and pus drained out. The opening led into the cyst cavity. It was enlarged, washed and drained. He left the hospital about a month after.

Case 13.—M., aged 49, female, Mohammedan, housewife. She noticed a small swelling in the right hypochondriac region some eight or nine years ago which grew slowly. The swelling became painful a year ago. The pain gradually increased daily and was keeping her away from work. It was worse on exertion. The swelling was about the size of a cricket ball and continuous with the liver at the site of gall bladder. She was anæmic and was getting occasional attacks of fever. Spleen enlarged. No jaundice.

She was treated for malaria for a fortnight and then operated on on 28th August, 1933. A cyst was found on the under surface of the liver; the gall bladder was small and pushed to the left side, and was healthy. The cyst was anchored to the abdominal wall and opened. It was found that the cyst communicated through an inch-wide hole with another cyst behind. The contents of this cyst were also removed and drained. During the treatment she got several attacks of malaria which did not respond

to quinine and she died of malarial cachexia about seven weeks after the operation.

Case 14.—S., aged 25, female, Mohammedan, housewife. She first noticed a swelling on right side of neck some six years ago. This very slowly enlarged and attained the size of a cricket ball. It was oval, painless and fluctuation was present, it was situated in the ... rated on ... and cyst removed.

Case 15.—H., aged 27, Mohammedan, male, shepherd. He noticed a painless swelling two years ago in the right pectoral region which increased slowly till four months ago when it suddenly enlarged with pain and fever. A few days later the swelling burst into the right axilla and was discharging. When he came to hospital, the swelling subsided. The discharge lessened when the swelling reappeared and became painful and after a few days it again discharged spontaneously.

Present condition—the right pectoral region is slightly more swollen. Swelling marked close to the sternum opposite 2nd and 3rd costal cartilages and painful, slightly red. Three sinuses in the axilla are covered with unhealthy button-like granulations, leading upwards and medially. No bone necrosis found. Operated on on 25th February, 1934, under chloroform for suspected caries of rib. Sinuses enlarged and scraped. The medial swelling was opened but no caries was found. During dressing one day a few daughter cysts came out with the discharge. The track was followed up and a few more cysts were found under the ... The cavity was scraped and kept in an abducted position. The wound healed in three weeks and the patient was discharged.

Case 16.—H., aged 30, Hindu, female, housewife. She had a swelling about the size of a walnut, a little above the outer part of the left eyebrow, which started as a small nodule. The skin was movable over it, and it was fixed below. Operated on on 14th March, 1934, under local anaesthesia and cyst enucleated. The under surface of the cyst was eroding the bone. Recovery immediate.

Case 17.—M., aged 22, Hindu, female, housewife. She noticed a swelling in the epigastrium some four or five years ago which had gradually grown bigger. At present it is of the size of a cricket ball. Fluctuation is present and it seemed continuous with the liver. She was operated on under chloroform on 1st April, 1934, through a paramedian incision. The cyst was in the left lobe of the liver, it was anchored to the abdominal wall. Contents consisting of cyst wall and a few daughter cysts with clear fluid were removed and the cavity drained. Recovery uninterrupted.

Case 18.—B., aged 20, Mohammedan, female, housewife. She noticed a swelling a year back in the left lumbar region close to the crest of the ilium. It was hard and increased slowly in size. Two months before coming to the hospital the swelling became more painful, attained a bigger size and grew softer. She had some fever, swelling occupied the left lumbar region from the iliac crest to the last rib. Bending was difficult and movements of the back limited. Local tenderness and slight oedema present. It was thought to be a case of caries of the ilium and operation was performed under chloroform and the swelling was found to consist of pus and degenerating cyst wall. It was removed and the cavity scraped and drained. The cyst was under cover of the latissimus dorsi, close to its origin from the ilium. She left the hospital cured.

Case 19.—A. B., aged 35, Mohammedan, male, agriculturist. He had a swelling about the size of the head on the left side of the neck posteriorly. He stated that it began as a small swelling, the movements of the neck were limited and he kept his head always drawn upwards and forward. Fluctuation was present and the tumour seemed fixed so lipoma was thought of. Opened under chloroform, a single cyst was found under cover of the subplatysma capitis muscle. The contents were evacuated and the cavity drained. Left the hospital cured.

Case 20.—G. H., aged 22, male, Mohammedan, bricklayer. At the age of 12, he had an attack of painful micturition. Suspecting a stone in the bladder (a common disease in the area), he consulted a doctor who passed a sound with negative result. The sounding was very painful and frightened him very much. Since then he had been getting occasional similar attacks but he never consulted a doctor being afraid of the small operation. During this time he had occasional attacks of retention of urine. This he learnt to relieve by applying cool mud over the hypogastrium. When he was twenty he noticed a small swelling above the pubis. He took it to be a full bladder as it disappeared after he had passed urine. The swelling always appeared whenever he got an attack of retention. These attacks became more frequent and the swelling began to persist and to grow upwards slowly. Six months ago all the symptoms grew worse. In spite of this he did not then consult a doctor. He had not passed any urine for the last four days before he was brought to the hospital. There was a swelling in lower part of abdomen reaching the level of the umbilicus. It was globular, hard and tender on pressure, fluctuation present; pressure caused a little urine to flow. Rectal examination revealed a globular swelling filling the whole pelvis. Its upper margin could not be reached. The lower margin was about an inch and a half from the anal margin. No definite diagnosis was made. A catheter could not be passed. A provisional diagnosis of full bladder was made. He was prepared for immediate operation. The usual incision for opening the bladder was made and it was found that the bladder was stretched in front of a cystic swelling and was empty. The bladder which had been opened was closed again and the incision was prolonged upward and a cyst attached to the upper and posterior surface of the bladder was found. This was opened and its contents removed and drained through the upper part of the incision. The lower part of the wound was completely closed and a catheter was left in the bladder. The patient passed large quantities of urine through the catheter after operation (probably from a hydro-ureter and hydro-nephrosis). For 24 hours after operation his condition was quite satisfactory, but then he suddenly collapsed, and died the same evening from shock.

Case 21.—M., aged 30, Mohammedan, male, agriculturist. He noticed a swelling over the left parietal bone two years ago. This grew slowly to about the size of a hen's egg. Fluctuation was present, and it was freely movable. Operated on under local anaesthesia, the cyst was enucleated. It was a typical single hydatid cyst. Healed by first intention.

Case 22.—K. B., aged 45, Mohammedan, male, weaver. He noticed a swelling in the abdomen some thirty years ago, immediately above the umbilicus. About the age of thirty it had grown to the size of a child's head and he got it tapped. It again filled up and five years later he had the same treatment. This time it enlarged more and became painful. As he did not find relief after these two tappings he abandoned the idea of further treatment. All this time he had been doing his work quite well. During the last two years he noticed that he was growing weak and losing flesh. This brought him to the hospital. On examination the swelling was found to occupy the middle of the abdomen, three-quarters of it above and one-quarter below the navel. The skin was black and hard from constant friction with his tools and instruments. The swelling was very hard and seemed heavy. With great pressure a depression could be made in it and the depression persisted. A provisional diagnosis of calcified cyst in the abdominal wall was made. Next day he was operated on through a paramedian incision. The cyst wall was very hard to cut and an opening about two inches long was made into it with great difficulty. The wall was all calcified and the contents resembled brown plasticine mixed with degenerated daughter cysts, red in colour. They were removed with a spoon aided by lavage. The cyst was drained but the cavity did not collapse. Calcareous flakes began to separate on the fifth day and all the calcified material had been evacuated by the fifteenth day. The cavity

granulated well and collapsed but the patient developed diarrhoea from which he died on the eighteenth day after operation.

Case 23.—N., aged 50, Hindu, female, a housewife. She developed a small swelling some twenty-five years ago in right upper part of abdomen where the gall bladder is located. She used to get attacks of pain resembling biliary colic at intervals. These attacks of pain got very frequent and at last became continuous. She had a small swelling in the right hypochondrium situated close to the ninth costal cartilage. It was movable with the liver and tender; slight jaundice was present. She had lost weight and her appetite was poor. Temperature was from 99°F. to 100°F. Pain is exaggerated with meals. All articles of diet that produce flatulence gave her trouble. A diagnosis of cholelithiasis was made and operation performed for removal of gall bladder. On opening the abdomen through the usual incision, it was found that the gall bladder was pushed to the left and was quite small and normal. In its place a cyst about the size of a closed fist was located in the right lobe of the liver; wall was partially calcified. It was anchored to the abdominal wall and opened, and the contents consisting of white fluid with daughter cysts were removed. She progressed well and after a fortnight a cast of the cyst partially calcified came out through the wound, after which it healed rapidly. The pain disappeared and she regained her health quickly.

Case 24.—B., aged 22, Mohammedan, female, housewife. She noticed a swelling in the epigastrium some four years ago which was slowly enlarging. She got married a year ago, and sought medical advice, but she did not agree to an operation. She had a child two months ago and after this the swelling became painful. The pain was colicky in nature and had no relation with food. It brought her to the hospital. The swelling was situated in the epigastrium and left hypochondriac region. It was dull on percussion except on its lower part and it seemed continuous with the liver in its upper part. Mobility was not marked and fluctuation was present. The swelling was exposed through a paramedian incision. It had no connection with the liver, the stomach was pushed down to the left and the cyst was found coming from the posterior abdominal wall from the site of the pancreas between the liver and stomach. The cyst was anchored to the abdominal wall and opened, the contents consisting of single cyst containing clear fluid was removed and the cavity drained. Recovery was uninterrupted except for skin excoriation, which persisted for about a month.

Case 25.—A. B., aged 30, Mohammedan, male, washerman. He felt pain some seven months ago between his shoulder blades. There was little swelling at that time. It slowly enlarged and two months ago the enlargement suddenly increased and kept him away from further work as it was very painful. The swelling extended from the root of the neck to the 8th rib on the right side with the shoulder blade raised over it. The movements of the arm caused pain. The skin was slightly red. Fluctuation was present and the swelling seemed lobulated. A provisional diagnosis of lipoma or cold abscess was made. Through a vertical incision it was found to be an exogenous cyst lying under the trapezius muscle. It was drained and the cavity healed uninterruptedly.

Case 26.—M., aged 50, Mohammedan, male, agriculturist. He noticed a swelling some 25 or 30 years ago in the right upper part of the abdomen. This did not give him any trouble till six months ago when it got painful. There was rigidity of the upper part of the abdomen over the swelling; fluctuation could not be made out on account of extreme tenderness. Diagnosis of cyst adherent to the abdominal wall was made and operation performed. Incision was made over the most prominent part of the swelling which was adherent to the abdominal wall. While separating the adhesions some pus came out which was removed and the cyst opened. Cyst was partially calcified and contained a white solid mass which was washed out with difficulty and the cavity drained. Recovery uninterrupted.

Case 27.—A Sikh woman was brought for post-mortem examination after a gun-shot injury. The spleen, which was completely disintegrated by the bullet, was found adherent to the diaphragm behind, and was very hard. It was separated and found to contain a calcified hydatid cyst.

Comments

In addition to the cases reported below 13 others in which a definite diagnosis of hydatid was made but operation was refused were seen in this period.

Epidemiological notes

Caste or race.—The area is mainly inhabited by Mohammedans, the relative proportion of Hindus to Muslims being 12 per cent to 88 per cent. There are also a few hundred Sikhs in the area. The incidence of the disease in the cases operated on is in the proportion of 4 Hindus, 22 Mohammedans and 1 Sikh, so that race has apparently no bearing on the incidence of the disease. Sex also shows no significant differences for there were 15 males and 12 females.

Age.—The question of age incidence is very difficult to ascertain in this area. There is hardly a man who knows his age, even approximately. A young man of 30 asked his age will often reply that his age is 4 or 5 years. So that the ages are not exact but only approximate and judged from the appearance of the patients. Roughly, it is a disease which comes under notice generally after the age of 20 up to old age. The disease is probably acquired in childhood or adolescence, but the latent period is uncertain.

Occupation and financial position.—The disease is of the poor in both races. The occupation among Muslims is generally agriculture. The cases include a beggar, a bricklayer, a washerman and a sweeper. The agriculturist invariably maintains a dog to keep watch over his animals at night; as cattle-lifting is very common. The Hindus are better off financially and have not to keep dogs but they are generally fond of dogs.

Drinking water.—The area is generally sandy. The wells are few and are shallow surface wells, and the water being brackish is only used in times of emergency. The area is supplied by irrigation canals and small channels, and the areas close to the hills by hill torrents, both of which run in summer only. About one-third of the population lives by the side of rivers from which they obtain all their water. They store water in open *kacha* ponds which serve their purpose at times of scarcity. These places are used by men and all other animals, and one is impressed by the amount of excreta of all kinds lying by the side of these ponds, a fruitful source of all kinds of bowel infections. Water stored in *kacha* pots (*gharas*) is not even looked after properly. I myself have seen on numerous

occasions in hot weather a dog lying next to such a pot and cooling his body by contact with the pot and the wet surface below.

Habits.—The people own large tracts of land—some situated at the foot of mountains irrigated by hill torrents and others close to rivers. Wherever they find suitable surroundings they move to that place. At such places they live in the open fields or in temporary straw huts. Under these insecure conditions they have to keep dogs. So these animals are in intimate association with man at all times.

Dogs.—The number of pariah dogs in a village is very great. For example, Rajanpur, where the dispensary is situated, had over 400 dogs with a population of 3,900. Here I was called upon to destroy those dogs at certain seasons. All those killed were subjected to a post-mortem examination for the presence of echinococcus. The total number examined was 156 with the following results:—

Number of dogs in which one or other worm was found	87
<i>Echinococcus granulosus</i>	45
<i>Tænia hydatigena</i>	29
<i>Toxascaris limbata</i>	22
<i>Opisthorchis caninus</i>	14
<i>Dipylidium caninum</i>	6

The number of echinococcus varied from a few to many thousands in different stages of maturity. In one case the strained specimen of stools resembled a thin sago pudding measuring 4 ounces consisting solely of those worms. Wild animals are in great number in the area, especially jackals and foxes. They are known to harbour these infections but no work has been done locally on these animals.

Cattle.—As a municipal medical officer I carried out the meat inspection for the municipality. I availed myself of this opportunity to estimate the hydatid infection in different animals.

Among sheep and goats in this area it is 1 per cent. Whereas among cows and bullocks 150 out of 168 examined were found to be infected. In 118 the liver was the seat of infection; 88 also showed the disease in the lungs and the next most commonly infected organ was the spleen in 68. The cysts varied in size from a mere speck to the size of a child's head and multiplicity was the rule. These were usually endogenous but sometimes exogenous, especially in the lung under the pleura.

Disposal of offal.—No special care is used to dispose of this infected material and it is eaten by numerous dogs that visit these places daily. The infection in these dogs was particularly high.

In small villages cattle are killed for meat occasionally and the same disregard of offal disposal exists there.

A BACTERIOLOGICAL STUDY OF CURDLED MILK (DAHI)

By C. L. PASRICHA

MAJOR, I.M.S.

S. LAL

and

R. K. GOYAL

(From the Department of Bacteriology and Pathology,
School of Tropical Medicine, Calcutta)

CURDLED milk or milk fermented by the action of certain bacteria has been used for many centuries in different parts of the world. The *yoghurt* of the Balkans, the *busa* of Turk-estan, the *kefir* and the *koumiss* of Russia and the *lebum* of Egypt are examples of curdled milk. These milk products are of great dietetic value and have been regarded as miraculous remedies for many ills. The fact that so many races make soured milk and use it copiously is by itself an excellent testimony to its usefulness. It was, however, largely owing to Metchnikoff that a great impetus was given to the multiplication of laboratory preparations containing cultures of lactobacilli. According to Metchnikoff, lactobacilli inhibit the growth of intestinal putrefactive organisms and thus prevent digestive troubles, rheumatism and generally prolong life. Considering the claims which were made on its behalf it is no wonder that lactobacillus milk came into demand in all civilized countries and people ate not only curdled milk but swallowed lactobacilli tablets which frequently contained no viable bacilli.

In India curdled milk (*dahi*) or one of its preparations has been used from time immemorial. In the earliest days of medicine, centuries before the Christian era, the great physician Sushruta drew attention to the great value of curdled milk and described in detail several different methods of preparation with their respective properties. The curdled milk is usually prepared by boiling the milk, cooling it to about 40°C. and then inoculating it with a small amount of curdled milk which contains the group of organisms known to yield a suitable product. Sometimes the milk is concentrated before inoculation, in which case the product is more nutritious but less refreshing than that prepared from unconcentrated milk. Often the curdled milk is diluted with water, churned and taken as a drink. There are two main types of curdled milk, the sweet and the

sour varieties. The consistency, odour and taste depend on a number of factors, the most important of which are the sugar used, the group of bacteria contained in the 'starter', the time taken and temperature at which the milk is allowed to coagulate. The curdled milk as generally prepared is semi-solid, consisting of finely-divided smooth curd which is said to be readily digested even by those who have more-or-less intolerance for ordinary milk. On removing the upper creamy layer there exudes a variable amount of clear whey-like fluid. It is interesting to note that the addition of agar agar to milk prior to the introduction of the starter results in the production of a firmer and richer looking product and we are informed that this is actually done in the preparation of certain commercial products.

The present investigation

Bacteriological examination.—In order to determine the bacterial content of curdled milk, 24 samples were collected from different sources. Smears were made from a well-mixed portion of each sample and were examined for the relative number and the type of organisms present. One gramme of each sample of curdled milk was diluted with saline to make a dilution of 1 in 10. From this, further dilutions were prepared and 0.25 c.cm. of 1 in a million, 1 in ten million and in a hundred million dilutions were added to tomato-juice agar (40 per cent fresh tomato-juice in 1.2 per cent nutrient agar at a pH of 6.0). These dilutions were found to give isolated colonies of lactobacilli. The plates were incubated for 48 hours at 37°C. in reduced oxygen tension with an addition of 10 per cent carbon dioxide. Representative colonies were studied from each plate.

The identity of the bacilli.—Lactobacilli resembling in their main characteristics the *Lactobacillus acidophilus* were isolated from each of the 24 samples. Streptococci were isolated from 23 of the 24 samples. The streptococci were of the *Streptococcus lactis* group. In the five samples of sweet curds examined yeast cells were present in addition to the lactobacilli and streptococci. Gram-positive spore-forming aerobic bacilli were found in only three samples. These bacilli were of a heterogeneous group and as many opportunities exist for contamination these strains were not further studied.

Although each sample of curdled milk was inoculated on a variety of media and incubated under different atmospheric conditions no other type of bacteria was isolated from any of the samples.

Morphology.—In smears prepared from curdled milk the lactobacilli were easily recognized as Gram-positive long bacilli with parallel sides and somewhat truncated ends. Filamentous forms which occur in laboratory cultures were not seen in smears made from the curds. Bacillary forms 3-4 μ in length, arranged singly or in pairs, in chains or in palisades, or long

(Continued from previous page)

Animals dying of various diseases are thrown away in close vicinity to the village where dogs have free access to them.

[Note.—This paper is of great interest for it indicates a state of affairs that is probably by no means exceptional in many rural parts of India, and supports an opinion we have held for a long time, namely, that serious helminthic diseases are far commoner in India than the published records show.—EDITOR, I. M. G.]

filamentous forms were seen in smears made from cultures on solid media. Some bacilli showed varying degrees of curvature and in some the ends were bent to form a curl. Bacilli with curled ends were found in all the strains of lactobacilli isolated. In fluid media the bacilli were thinner and more variable in length and shape; bacilli from the surface of the medium were short and stumpy whereas the deposit consisted of a mass of filamentous network.

Growth in different media.—The lactobacilli either did not grow or grew poorly on ordinary laboratory media; none of the strains grew on MacConkey's bile-salt lactose neutral-red agar. There was good growth in 1 per cent glucose agar and 1 per cent glucose broth, and in the latter medium there was a reduction of pH from 7 to 5 in 24 hours. Tomato-juice agar or whey agar was found to be satisfactory for the isolation of lactobacilli.

On tomato-juice agar or whey agar lactobacilli grew as isolated colonies, irrespective of the amount of inoculum. After 24 hours at 37°C. the colonies were small, about 0.5 mm. in diameter. They were raised, opaque, somewhat greyish in colour, rounded with an irregular edge, granular in appearance, pasty in consistency and with a glistening surface. After a week some of the colonies attained a diameter of 3-4 mm. and differentiation occurred into a thicker raised knob-like centre and a thinner periphery with a clearer intermediate zone. All the strains were rough and could not be suspended in normal saline or water.

All the strains of lactobacilli grew best in reduced oxygen tension with the addition of 10 per cent carbon dioxide. After repeated subculture in the laboratory feeble growth was obtained both under aerobic and anaerobic conditions. The optimum growth was at pH 5-6. In nutrient agar or broth of pH 5-6 growth was readily obtained. The majority of the strains failed to grow in media with pH above 7. The optimum temperature for growth was 37°C.: slight growth occurred at 16°C. to 22°C. The biochemical reactions of 15 strains of the lactobacilli were studied. All strains fermented glucose, whilst approximately 50 per cent of the strains fermented lactose, 70 per cent fermented saccharose and maltose, 20 per cent fermented mannitol and 10 per cent fermented salicin. Indole was not produced by any strain. Milk was clotted by all strains usually after 48 hours, in four strains after 72 hours. In only two strains was milk clotted within 24 hours. The strains were compared with type strains of *L. acidophilus* and *L. bulgaricus* and the majority of the strains isolated resembled *L. acidophilus*.

Other organisms present.—Streptococci were isolated from 23 of the 24 samples examined. Gram-positive cocci arranged in groups of two or in short chains were seen in films made from curdled milk. They grew readily on nutrient

agar both under aerobic and anaerobic conditions. Surface colonies were of two types, (a) round, convex, opaque with a smooth and glistening surface and (b) opaque and granular often encircled by a thick annular ring. The deep colonies were lenticular, opaque with a uniform border. The majority of the strains fermented lactose, glucose, maltose, mannitol, salicin and saccharose with the production of acid only. Acid and clot were produced in litmus milk within 18 hours and the clot was firm in consistency.

Two types of yeast cells were isolated: type A was found in three of the five samples of sweet curds examined and type B was present in all the five samples. Colonies were isolated on tomato agar and attained a size of 1 to 2 mm. in 24 hours. The colonies of type A, on tomato-juice agar, were light grey in colour, round, convex with a series of concentric rings on the surface. These fermented glucose with the production of acid and gas and failed to ferment lactose, maltose, mannitol, dulcitol, saccharose and salicin. There was no change in litmus milk. The colony of type B grown on tomato-juice agar was round, smooth and white in colour, and after incubation for four days there were projecting feathery outgrowths from the periphery of the colony. This type fermented glucose, maltose, mannitol, saccharose and salicin and did not ferment lactose and dulcitol. Litmus milk was turned alkaline.

Storage.—The various samples of curdled milk contained from 200 to 1,000 million viable lactobacilli per c.cm. on the day the samples were obtained. When stored at ordinary room temperature (about 35°C.), there was at first a slight increase in the number of lactobacilli but within 24 hours the number of viable lactobacilli had become negligible and many of the samples were grossly contaminated, markedly acid and unpleasant to taste. The spoilage was due to spore-forming bacilli and fungi. Samples kept at a temperature approximately 16°C. to 18°C. and in a refrigerator (about 5°C.) remained unspoiled and pleasant to taste for periods varying up to 9 days. Within 24 hours there was a reduction by about 50 per cent in the number of viable lactobacilli. The viable count of lactobacilli in samples kept for 9 days at 16°C. to 18°C. and at refrigerator temperature was approximately the same; there was a reduction by about 75 per cent in the number of viable lactobacilli. Although Rettger (1935) regards a temperature range of 16°C. to 20°C. as the most favourable for storage of curdled milk and considers that comparatively low temperatures (5°C. to 15°C.) are unsuitable, in that it reduces the viability of the lactobacilli, our experience has shown that there is no appreciable difference in the viable count of lactobacilli in the samples maintained at 16°C. to 18°C. and at refrigerator temperature.

ARTERIOGRAPHY

By R. DEMEL, M.D.

Professor of Surgery and Director of the Surgical Department, Krankenanstalt Rudolfsstiftung, Vienna

In my present paper I wish to consider certain disease processes which have increased in number in the past few years, not only among hospital patients, but also in general practice. The processes in question are due to pathological changes in the blood vessels of the limbs.

(Continued from previous page)

Results of administration.—Curdled milk prepared with standard strains of *L. acidophilus*, *L. bulgaricus* and local strains was given to different individuals. Approximately 24 ounces of curdled milk were consumed daily by each subject for a period of six weeks. During this period lactose was given freely. The lactobacilli which were recovered from the stools could not be identified with the lactobacilli administered and there appeared to be no marked increase in the number of lactobacilli in the stools.

On the assumption that an intestinal strain of lactobacillus which has been recently isolated should adapt itself to intestinal environment more rapidly and more completely than one that has been propagated on artificial media in the laboratory, five individuals were given large daily doses of curdled milk prepared with freshly-isolated intestinal strains of lactobacilli. Although there was an increase in the number of Gram-positive rods in faecal smears there was no marked alteration in the intestinal flora and the lactobacilli isolated could not be identified with the strains administered.

Summary.—Twenty-four samples of curdled milk collected from different sources in Calcutta were examined for their bacterial count.

Lactobacilli resembling in their main characteristics the *L. acidophilus* were isolated from each of the samples.

Streptococci resembling *Streptococcus lactis* were isolated from 23 of the 24 samples.

Yeast cells were present in the five samples of sweet curdled milk examined and were absent from the sour variety of curdled milk.

Curdled milks prepared with standard strains of *L. acidophilus*, freshly isolated strains from a number of commercial curdled milks and from human intestines were administered to different subjects along with adequate amount of lactose. The organisms isolated from the stools could not be identified with the bacilli administered. There was no evidence that implantation of lactobacilli had occurred in the intestine.

REFERENCE

Rettger, L. F., Levy, M. N., Weinstein, L., and Weiss, J. E. (1935). *Lactobacillus acidophilus and its Therapeutic Application*. Yale University Press, New Haven.

The patients are chiefly men of relatively young age otherwise fit for work. Their lot is pitiable, not only because of the considerable pain they suffer, but also because medical treatment may bring so little relief that amputation eventually becomes the only available remedy. It was to prevent such drastic treatment that the present investigation was undertaken. Before it, we had already employed over some years the customary modes of treatment, such as subcutaneous and intravenous injections of sodium nitrite, papaverin, callicrein and yohimbine, the local application of heat, and irradiation of the appropriate spinal cord segments of the diseased limb by x-rays. None of these methods of treatment was successful. Periarterial sympathectomy and sympathico-diatheresis done by Doppler's method also failed. We therefore next turned our attention to arteriography in the hope that x-ray pictures of blood vessels would lead to advances in the diagnosis of vascular disease in the limbs.

Arteriography

Frank and Alvens were the first to demonstrate blood vessels in the living animal. They injected a bismuth-ether-oil solution into the circulation of dogs, and observed by the x-ray screen the oil drops as they were carried by the blood. Later, in 1923, Berberisch and Hirsch used opaque fluids and obtained x-ray demonstrations of blood vessels in man. Their example was followed by others in America, Portugal and France using concentrated halogen-salt solutions.

In 1929, in co-operation with Sgalitzer and Kollert, I chose uroselectan to show up the arteries. This drug was already known to us through the reports of Lichtenberg and Swick. It has been used by intravenous injections to obtain x-ray pictures of the urinary organs (intravenous urography). In more than 100 cases uroselectan was tolerated without any ill effects, although urography demanded a multiple of the amount required for arteriography. Generally speaking, 20 c.cm. of uroselectan sufficed for arteriography, but if these were not enough another 20 c.cm. were injected. We gave up the use of uroselectan, however, because the instability of its solutions made it necessary for fresh ones to be made before each operation. In consequence we turned to abrodil in 20 per cent solution. This is stable, and we have now used it for many years.

Technique of arteriography

The artery is first exposed under local anaesthesia. The strictest aseptic precautions are required because of the defective blood circulation in these patients. When the disease process is in the leg the femoral artery is exposed below Poupert's ligament. When the disease is in the arm the axillary artery is exposed just enough to permit an injection being made into it. There is no removal of the adventitia as is the

ease with periarterial sympathectomy, and there is no greater arterial exposure. It is necessary to expose the artery because of the frequent absence of pulsation in the vessels, and because of the possibility of error arising from percutaneous injection.

A wick of cotton-wool placed round the vessel enables the assistant to hold the vessel fast and raise it for the injection. The needle used must not be too fine, and should be pulled out immediately the injection is over. The site of puncture is then covered for a short time with a sponge-stick which has been dipped into liquid paraffin. This quickly stops any bleeding.

Previous to the operation a case wrapped in a sterilized towel and containing the x-ray plate is placed under the operation-limb. The x-ray tube of a portable apparatus is also so arranged that the exposure can be performed when the surgeon requires it. This is towards the end of the injection. The wound is closed after the picture has been taken.

The patient is subsequently kept in bed for six days. The stitches are then taken out and he is allowed to get up. The operation is generally painless, but sometimes a spasmodic pain may be felt at the end of the injection. This pain disappears in about 10 seconds.

Diagnostic value of arteriography

Arteriography can be expected to show which of the vascular areas of a limb is most affected by the disease processes, and to throw light on the type of the primary disease together with the extent of the impairment of the circulation. Further arteriography, by giving the exact localization of an embolus, facilitates subsequent operative treatment. The site and shape of an aneurism are also revealed, and the knowledge thus obtained usefully guides subsequent operative procedure. Moreover, we can obtain characteristic pictures of narrowed lumina and occlusion of vessels in such conditions as thrombus, spasm, arteriosclerosis and endarteritis obliterans. If arteriosclerosis involves a stenosis we may obtain a differential diagnosis between involvement of the intima or media. Smooth and trough-shaped narrowings in the pictures of the liquid in the vessels indicate a thickening of the media, while jagged projecting shadows indicate proliferation of the intima. We have further learnt that vessels with abrupt curves and narrow sinuosities are pathological, for sinuous lines imply arterial obstruction even though the lumen of the vessel seems normal.

Arteriography also reveals the collateral circulation in cases of complete obstruction, and the degree of development of such collaterals enables the recent to be differentiated from the long-standing occlusion. We may thus become aware of the existence of favourable circulatory adjustments in cases of complete and long-standing intermittence of a main vessel.

In contrast with this we cannot deduce good nutrition of a tissue from the filling of its arteries, an error we made when we first started our work. It is much more important to consider the changes of the vascular walls that are revealed by the fillings (defects in the vascular wall, tortuous vessels, etc.). Such are the changes to be considered when assessing the state of nutrition in their area. Increasing experience so enabled us to understand the significance of these changes in the vascular walls that we were eventually able to determine the correct level of amputation before an operation for gangrene.

Uniform strictures in the fluid picture and smooth border lines in the narrowed area indicate spasm. In these cases we have found out why gangrene does not occur even though large sections of blood vessel are empty. The cause lies in the transient character of the spasm.

Stenosis caused by spasm may simulate any other stenosis. To differentiate spasm from an organic stenosis, 0.06 gm. of papaverin or eupaverin (Denk) is injected subcutaneously. Ten minutes later intra-arterial injection and x-ray exposure are repeated. Any defects of the vessel wall or strictures seen in the second x-ray plate are due to organic disease of the vascular wall because spasm is abolished by papaverin.

The therapeutic effect of arteriography

In the early days of our work on arteriography, an important case came under my observation. An Italian officer, aged 37, had an upper left arm amputation. Two years later the type of trouble which had demanded this amputation occurred in the right hand also. The patient suffered much and required large doses of morphia to alleviate his pain. When first seen by me there was no pulsation palpable in the right forearm, the fingers were cyanotic and swollen, and they could be moved only with great effort.

A diagnostic arteriography was done, and revealed only slight fillings of the ulnar and interosseal arteries. The radial artery and the vessels of the hand were imperceptible.

But, to our astonishment, subsequent to the arteriography the patient was so relieved of his pains that he no longer required morphia. In addition, the changes in the hand regressed, and his arm was saved. This improvement has persisted for over six years, and the patient now uses his arm without difficulty.

This was the first case that demonstrated a therapeutic influence of arteriography. After that striking case I paid special attention to this therapeutic action. Experience has shown me what now follows.

Patients with thrombo-angiitis obliterans (Burger), endarteritis obliterans, peripheral arteriosclerosis with angiospasm who, previous to arteriography, had suffered intense pains requiring large doses of narcotics did not need them after. The diseased limb lost its cold and

pallid appearance, and grew warm. I also observed that bedridden patients and those barely able to walk a hundred metres, because of pains and spasms, could move and work without trouble after arteriography had been done. The capillary microscope demonstrated that these clinical improvements were accompanied by a re-establishment of normal conditions in the capillaries. The capillary loops were distinctly seen and the blood circulated properly in them.

Some time after we had made our observations, J. Schüller in 1933 also observed a valuable therapeutic influence of arteriography. My own observations extend over many years and have been made on 70 patients. I therefore feel justly entitled to emphasize the therapeutic influence of arteriography.

It should be clearly understood that all our patients had previously been treated elsewhere by the usual methods. They had been treated internally, and physically with radio short waves and x-ray irradiation. Some of the patients had undergone Leriche's operation, others had been brushed with phenol in accordance with Doppler's technique. None of these treatments was successful, and the suggestion of amputation at the upper thigh was actually the cause which led some of the patients to my consulting room.

In the cases considered above we were not dealing with functional disturbances of limbs due to spasms and pains; coldness, lividity and bluish discoloration, and even sometimes circumscribed gangrene indicated distinct circulatory changes. We did not deal with incipient vascular disease, but with definitely established pathological changes of advanced nature. In the arteriographic pictures of the fluid in the vessels the defects generally manifest were several centimetres long. The most frequent sites of serious change were the central portion of the femoral artery and that portion of the femoral artery which lies about a hand's breadth above the knee joint, just in the adductor canal.

Quite apart from relief of pain and the vanishing of pallor, I observed also a curative action on the skin, even in cases of long-standing loss of tissue. Thus, it sometimes happened that a line of demarcation was established in a gangrenous toe. The toe then fell off, or was removed by operation. Afterwards the wounds healed up.

But I must also mention that these remarkable changes in the clinical picture were rarely accompanied by changes in the palpability of the affected arteries. If we could not trace an artery by palpation previous to arteriography, we could not do so after, although the other conditions were better.

Prof. Pick, at the suggestion of Sgalitzer and myself, experimented on animals in the Pharmacological Institute with the idea of obtaining an explanation of the therapeutic influence of arteriography. He found that arteriography

with abrodil and perabrodil brings about a persisting and distinct dilatation of the thin vascular branches.

It must further be emphasized that arteriography can be repeated at will and at the same site. A second arteriography is as beneficial as the first. These second arteriographies revealed a better development of the collateral circulation corresponding with the duration of the disease. These collaterals bridged over the defective portion of the main artery, and were of supreme importance for the maintenance of the circulation.

The unfortunate admission has to be made, however, that arteriography is not uniformly a therapeutic success; actually, only one-third of the patients obtain benefit therefrom. Nor can I yet accurately foretell whether a particular patient will benefit or not. Benefit is reasonably certain in cases of angiospasm, and above all in cases of endarteritis and thrombitis obliterans.

At the same time it is to be observed that arteriography has spared many of my patients from amputation. When the arteriography was performed, not only was amputation deemed urgent, but there was also no hope either for relief of pain or of any restoration of working capacity.

A Mirror of Hospital Practice

AN UNUSUAL CASE OF MULTIPLE STONES IN THE URETER

By K. S. THAKUR, M.R.C.S. (Eng.), L.R.C.P. (Lond.),
 D.T.M. & H. (Camb.)

LIEUTENANT-COLONEL, I.M.S.

Surgeon-Superintendent, Shambhunnath Pundit Hospital,
 Calcutta

MOHAN SINGH, an ex-sepoy, who had seen service in France was admitted to my wards on 13th November, 1936. He complained of a swelling in the right hypochondrium and on the right side of the epigastrium. On investigation, it was found that the patient had a big

stone in the pelvis of the left kidney and had a few in the lower part of the right ureter with the right kidney very much damaged and probably hydro-pyonephrotic. The function of the left kidney was found to be not very much damaged. I therefore decided first to operate on the left side.

On 29th January, 1937, I made a long lumbar incision on the left side in order to get a good view of the posterior aspect of the renal pelvis. After incising longitudinally the posterior wall of the pelvis of the left kidney, a rough irregular stone weighing one ounce was removed after considerable difficulty, as part of the stone was firmly embedded in kidney tissue. After putting a few stitches to close the incision in the renal pelvis, the wound was partially closed and a drain left at the upper end. There was a fistula for a time but ultimately the wound closed up completely.

On taking skiagrams on different occasions, the position of stones on the right side at the lower end of the ureter was found to be constant. I therefore decided to make a para-rectal incision and reach the ureter extra-peritoneally. The uppermost stone was soon located and was found to be movable in a dilated

The pathological curator of the Royal College of Surgeons of England to whom I sent a report of the case has kindly sent me the following comments :—

1. From their colour and facets, the stones appear to be urate and uric acid.
2. Since ureteric stones always originate in the kidney, the presence of unopposed facets would suggest a fairly long stay in the renal pelvis before descent into the ureter.
3. It is remarkable that the renal function on the left side was so little impaired in view of the almost complete obstruction of the ureter, more especially as it is probable that the right kidney would never recover its function after gross and prolonged infection.

portion of the ureter. After incising the ureter longitudinally this was easily removed. A large quantity of thick whitish fluid gushed out of the wound. When all the fluid had drained away I located two more stones in the right ureter near its entrance into the bladder. These were absolutely fixed and could not be moved. With the help of an assistant's finger in the rectum to steady them, I incised the ureter lower down over them and with great difficulty succeeded in dislodging and removing them.

After the second operation the patient's condition was low for some time, but ultimately he recovered completely and was discharged cured from the hospital on 30th June, 1937.

It may be noted here that, before his discharge, his urine was clear and the swelling on the right side had gone down completely.

A point of interest to be noted is that the uppermost stone has two facets, one on the superior and another on the inferior surface. Similarly the lowermost one has two facets. This phenomenon is probably associated with the movements of the stones in the early stage of their formation, as otherwise in the absence of stones above and below it is hard to account for the facets being present on the superior surface of the uppermost stone and inferior surface of the lowermost.

Bilateral renal calculi are not uncommon in this country but I do not remember seeing a case in which all the stones on one side had passed into the ureter, and I feel sure that a published record of the case would be of interest to your colleagues'.

PERFORATION OF THE ILEUM IN SUSPECTED AMBULATORY TYPHOID TREATED WITH ESTABLISHMENT OF DRAINAGE AND FÆCAL FISTULA AND SUBSEQUENT ENTERECTOMY

By S. R. GORE, L.M. & S.

Honorary Surgeon and President, The Hubli Co-operative Hospital Society, Hubli

B. D. N., aged 35, was admitted for 'acute abdomen' into the hospital on 13th August, 1936.

He gave a history of fever for about two weeks previous to admission but said he was not confined to bed till the day before when he had acute pain in the abdomen.

Condition on admission.—Temperature 99°F ., pulse 124 and respiration 40 per minute, restless, dry brown tongue. Abdomen tender, distended and board-like. Absolute constipation.

With the history of fever and evident signs of peritonitis diagnosis of perforation was made and laparotomy was done immediately. The perforation was found to be about nine inches proximal to the ileo-cæcal junction and it was found to be about an eighth of an inch in diameter with irregular edges; intestine around the hole was brittle and attempts at closure were futile. It was therefore fixed to the abdominal wall and drainage established in the right kidney pouch and pelvis; the abdomen was gently irrigated with saline and the patient put in Fowler's position. He was discharged with a fæcal fistula on 18th November, 1936, as his general condition was not good enough to allow an enterectomy for the closure of this artificial anus. When discharged he used to pass about two-thirds of the excreta by the anus and the rest by the fistula.

He was re-admitted on 1st March, 1937; his general condition was good and he looked as if he had gained at least fifteen pounds in weight. The fistula was now discharging a little less but evidently there was no chance of its closing without intervention.

He was therefore operated on on the 5th March and the fistulous tract which admitted easily a number 12 cervical dilator was removed by enterectomy and end-to-end anastomosis was done.

Patient recovered without any subsequent trouble except that he developed slight jaundice on the sixth day of the operation having had a slight rise of temperature up to 100°F. on the previous day.

Fractional doses of calomel relieved him in a few days, the wound healed by first intention and the patient was discharged cured on 12th April.

I am reporting this case because cases of perforation rarely come under the surgeon and even when seen the relatives rarely permit an operation to be done. Of course, in this case, as the typhoid* was ambulant it was not diagnosed before the patient came to hospital and the general condition of the patient also was fairly good so far as emaciation and other typhoid conditions were concerned, but he had had definite peritonitis with the usual symptoms, thready pulse, dry brown tongue and rapid respirations, of over 24 hours' duration.

* It does not appear that typhoid fever was definitely diagnosed even after admission to hospital.—Eaton, I. M. G.

UNUSUAL CASE OF URETHRAL STONE

By P. P. SHETH, F.R.C.S. (Eng.)

Honorary Surgeon, Civil Hospital, Ahmedabad

A MALE patient, N. V., aged about 60, was admitted into the Civil Hospital, Ahmedabad, on 16th October, 1937, with a complaint of dribbling of urine continuously from the scrotum and perineum for four months.

Previous history.—He had a fall from a tree from a height of 20 feet about eight years ago causing a simple fracture of the neck of the left femur. Fifteen days later he developed retention of urine and fæces but was treated and cured. As a result of this fracture he got a deformity on the left side and had a limp. Since then he has had no other complaint until he noticed a painful swelling in the perineal and lower part of scrotal regions which also led to retention of urine, about four months ago. After a few days, both the swellings burst and there was discharge of pus and

urine. During the four months similar abscesses went on forming and bursting until they formed multiple sinuses which discharged pus and urine. The urinary flow thus stopped coming through the external urinary meatus. Patient denied any history of gonorrhœa or syphilis.

Condition on admission.—The patient was emaciated and had a pulse of about 92 on admission; the circulatory, respiratory, digestive and nervous systems appeared normal.

Examination of the affected part.—The skin was shining, pigmented and thickened in the region of the scrotum and the perineum and there were five sinuses discharging urine and seropurulent matter. The skin was adherent to the testes; both the cords were slightly thickened, inguinal glands palpable on both sides and a catheter could not be passed for more than three-quarters of the length of the anterior urethra. Per rectum there was felt some hardness in the prostate region but there was no pain or tenderness.

Provisional diagnosis.—Stricture of urethra.

The patient was operated on under spinal anaesthesia (stovaine 2 c.cm. of 2 per cent solution) on 20th

Urethral stone: weight 79.5 grammes.

October. A perineal incision was made in the line of the membranous urethra, and after passing the Wheelhouse staff the membranous and a part of prostatic urethra were laid open. On further exploration of the region an abnormally big stone was detected occupying the whole of the prostatic and membranous urethra and obscuring the pubic arch. It was removed, the bladder irrigated and the usual perineal drainage done. The surrounding fibrous mass was excised and the wound partially stitched and dressed and then bandaged.

The stone was $2\frac{1}{2}$ by $5\frac{1}{2}$ inches in diameter and weighed 79.5 grammes.

After the operation from 21st to 24th the general condition of the man remained very weak. He was at times delirious, sometimes getting out of bed, and the quantity of urine was less. The patient was kept on urinary antiseptics and sedatives with glucose and barley water by the mouth. On the 23rd he was given intramuscular cytotropin which was continued to the 26th. He showed signs of improvement from the 26th and since made a good recovery. His perineal tube was removed on 27th and a large rubber catheter (Nom) inserted through the penile urethra and the lower wound allowed to heal. He was making slow progress, but as a result of malnutrition and advanced age he died on the 16th November.

The case is of interest from the unusual site and size of the stone. At first it appeared as if it was a bony growth and gave much difficulty in removal.

FEBRUARY

THE ORGANISM AND THE ENVIRONMENT

THE medicine that we practise to-day is essentially a science, that is, to quote from the *Shorter Oxford English Dictionary*, a 'branch of study which is concerned with observed facts systematically classified and more or less colligated by being brought under general laws, and which includes trustworthy methods for the discovery of new truth within its own domain'; it is neither a religion based on unalterable dogma, nor an art dependent entirely on the special interpretation of the individual, though both faith, associated with religion, and the skill of the artist are essential qualities in the make-up of the practitioner of the science of medicine.

The discovery of new truth must, however, include the rediscovery of old truth, and we need not reproach ourselves because the 'advances' in our science are sometimes nothing but orderly retreats. What was the truth yesterday is often not the truth to-day and yet may again be the truth to-morrow.

From the days of Hippocrates to those of Sydenham, in the consideration of the health of the individual, although the importance attached to airs, waters and places varied from time to time throughout these twenty odd centuries, it was always considerable, and it continued to be so even up to the middle of last century, but with the dawn of the bacteriological era a change in our attitude became apparent; airs and waters were considered of importance only with reference to the bacteria they contained, or did not contain, and places were valued only by their sanitary (*in sensu restricto*) qualities.

'How can this be?' we can hear critics say 'in view of the fact that tropical medicine, where, as the name itself suggests, the whole emphasis is on locality, first appeared as a separate branch of our medical science, during these years?' This is true, but surely tropical medicine as it has been studied and taught during the last half century provides us with the best example of the influence of the bacteriological, or rather parasitological in this instance, outlook; the miasma of the nineteenth and earlier centuries gave way to the anopheles-breeding swamp, and noxious emanations to fly-borne bacterial infections.

But to-day everywhere there are signs of the returning swing of the pendulum and a revival of interest in airs, waters and places. The parasitic theory of disease is unassailable, but we are realizing, more and more, that the parasite is not the only factor that determines

disease, that not the seed only but the soil must be considered, that the reactions of the organism itself to parasitic invasion are equally, if not more, important, and that in determining the nature of these reactions no single factor is more important than the environment in which that organism lives.

The study of physiology is an essential part of the medical training and yet little attempt has been made to study tropical physiology; up to the present we have been content to build our tropical pathology on the very doubtful structure of a physiology of temperate climates that has been patched here and there to suit tropical conditions. Even these patches are usually dependent on guess-work and not on systematic investigation. There are numerous examples of our ignorance in the matter of tropical physiology; we are still uncertain whether such a fundamental process as basal metabolism is altered by residence in the tropics, and, although for years it has been tacitly assumed that the hæmoglobin standards of the inhabitants of tropical countries are distinctly lower than those of the inhabitants of temperate zones, when the subject was investigated this assumption was found to have no basis on fact. Similarly, the low gastric acidity of rice-eating races living in the tropics has been shown to be a myth (*vide p. 65* in this issue).

The subject of Colonel Chopra's very interesting presidential address at the opening of the physiological section of the Indian Science Congress was the effect of climate on the physiology of the individual, and naturally it was the tropical climate with which he was mostly concerned.

We published the first part of this address in our January number (p. 40) and the remainder will be found in the present issue (p. 102). We hope that this address will have the effect of stimulating an interest in this very important subject and of encouraging those who have the opportunity to carry out research work in order to fill some of the many gaps in our knowledge of tropical physiology.

THE KING-EMPEROR'S FUND

THE attention of our readers is drawn to the appeal made by Her Excellency Lady Linlithgow for contributions to establish a fund which will be devoted to combating tuberculosis in India.

The subject is one in which His Majesty the King-Emperor has taken a personal interest and he has consented to the fund bearing his name.

We have always taken a very special interest in tuberculosis, which we look upon as one of the 'tropical diseases' of the future; whereas it is showing a slow but steady decline in western countries, all the available evidence indicates a rapid extension in India. Last year we issued

a special tuberculosis number of the *Gazette* and this year we propose again to publish one number devoted mainly to this subject.

The object of this fund should have a particular appeal to readers of this journal, as nobody can be more painfully aware of the ravages of this disease in India than members of the medical profession. The medical profession can help the cause of tuberculosis control in many ways and as its members are on the whole poor they cannot be expected to contribute largely to this

fund; nevertheless every contribution, however small, helps, and we hope that every one of our readers will endeavour to make some small contribution. We suggest that those of our readers who have not already contributed should send their contributions through our editorial office for forwarding. Any such contribution (of one rupee or over) received will be acknowledged in the pages of this journal and forwarded to the central fund as a contribution from readers of the *Indian Medical Gazette*.

Special Article

THE PHYSIOLOGY OF THE INDIVIDUAL IN THE TROPICS*

Part II

By R. N. CHOPRA, C.I.E., M.A., M.D., SCD., M.R.C.P.
BREVET-COLONEL, I.M.S.

Honorary Physician to the King
Director, Calcutta School of Tropical Medicine

(Continued from the January 1938 issue, p. 40)

EFFECTS ON THE DIGESTIVE SYSTEM

Atonia and stasis.—It has frequently been observed by Europeans coming to the tropics that there is a definite impairment of appetite and a lessened desire for animal food. Though this may indicate a diminished power of digestion, it is probable that the disinclination for animal food may be an adaptive response to a lower caloric need in the tropics. There is also a tendency to an atonic condition of the gastro-intestinal tract, as evidenced by an increased tendency to stasis with resultant constipation and gaseous distension. This may be due to sedentary habits and lack of exercise though it is perhaps largely due to the fact that Europeans in the tropics are apt to follow their old dietary habits suited to temperate climates and do not take enough carbohydrates, vegetables and water to provide for the roughage. On the other hand, it is possible that the high environmental temperature in the tropics leads to a vaso-dilatation of the skin capillaries and a reflex vaso-constriction and anæmia of the splanchnic area, resulting in diminished gastric and biliary secretions, and possibly also in an atonic condition of the stomach and intestines. Muller and Peterson (1936) called attention to the fact that, with skin stimulation, the activity of the mucous membrane of the stomach and gastro-intestinal tract was decreased, but with lessened activity of the skin (as with cold) the functional activity of the mucous membrane of the gastro-intestinal tract was increased. It is probable that the inhabitants of warm climates make an appropriate physiological and dietetic accommodation by the greater use of condiments. Spices in solution are known to increase the activity of the villi and secretory glands, and the free use of condiments in the tropics may be an expression of the greater need for gastro-intestinal stimulation where skin activity is normally unduly accentuated.

Gastric acidity.—A general impression seems to prevail that the gastric acidity of rice-eating Indians is lower than that of meat-eating Europeans. Napier and Das Gupta (1935) carried out a fractional gastric analysis on a number of normal Indian male and female subjects and found that on the whole their gastric acidity was higher than in normal Europeans. This is

contrary to expectations, for hot climate and vegetarian diet are both believed to be factors that tend towards decreasing gastric acidity. No explanation of this phenomenon is yet forthcoming.

Bacterial flora.—Bacteriologists have claimed that the bacterial flora in the intestines of inhabitants in the tropics are different from those of colder climes. Arnold (1934) has shown that the bacterial flora of the lower intestinal tract vary with external temperatures and hence it is natural to expect a difference between those found in the tropics and the cooler regions. As the nature of the food is also known to influence the relative proportions of the various bacterial groups in the intestinal flora, and as the predominant dietary constituent in the tropical inhabitants is carbohydrate, the claim has much in its favour. Workers in this field appear to agree that an animal protein diet encourages the growth of proteolytic types, whereas the addition of lactose and dextrin stimulates the development of aciduric micro-organisms. Normally, a sufficient amount of lactose in most instances will cause a complete transformation of an ordinary mixed flora into one consisting predominantly of streptococcal and lactobacillary types. It has, for instance, been recently shown that banana powder, apple powder, and raisins, when fed to white rats subsisting on a high protein diet, consisting exclusively of raw chopped beef, produce a change in the intestinal flora from one in which non-aciduric bacteria predominate to one in which *Lactobacillus acidophilus* is the outstanding organism. It has been further pointed out that the simplification of the intestinal flora varies directly with the hydrogen-ion concentration, a pH of 7.0 being characteristic of a gas-producing proteolytic type, whereas an increasing acidity is characterized by a diminution of proteolytic types and the replacement by the aciduric types. It is evident, therefore, that a diet containing sufficient carbohydrate is capable of effecting a complete turnover from a heterogenous Gram-negative type of flora in persons fed on high protein diet, to a flora markedly simplified and Gram-positive, inducing coincidentally a change in the hydrogen-ion concentration from nearly neutral to distinctly acid.

Recent work (1937) on the hydrogen-ion concentration of faeces of different classes of persons living in Calcutta shows that, whereas the reaction of the stools of most of the Bengalis is acid, those of the Europeans, Anglo-Indians and Marwaris are mostly alkaline. Although the Marwaris are vegetarians and live on a predominantly carbohydrate diet, they consume very little rice and take more wheaten bread (*chapati*). It would appear that the consumption of rice produces an acid reaction in the large intestine while wheat produces an alkaline reaction. When Bengalis were put on bread, and rice was cut off, the reaction of the stools changed from acid to alkaline in most cases. In view of the acidity of the stools, it was thought likely that aciduric organisms would predominate in the stools of Bengalis, but surprisingly enough *Lactobacillus acidophilus* could not be isolated.

* Abridged from the Presidential Address of the section of Physiology, 25th Indian Science Congress, Calcutta, 1938.

With regard to bacterial flora in the normal intestinal canal of Indians and the differences, if any, that may exist in this direction between Indians and Europeans, our knowledge is far from complete. In an extensive survey of the bacterial flora carried out in the School of Tropical Medicine, a non-lactose fermenting Gram-negative bacillus (*B. pseudo-carolinus*) was frequently isolated from normal healthy individuals in Bengal. This organism is not present in the stools of Europeans who have never come to the tropics. It appears to have no definite relationship to the dysentery group of organisms excepting that it is sometimes lysable by dysentery phages. In this connection it is interesting to note that *Monilia psilosis* which according to Ashford (1924) is the causal organism in sprue is frequently found in Calcutta in the stools of persons who are definitely not suffering from this disease. It is not possible in the present state of our knowledge to state definitely whether such organisms are normal inhabitants of the intestine or whether they play any part in the causation of the disease.

EFFECTS ON THE RESPIRATORY AND CARDIOVASCULAR SYSTEM

Frequency and depth of respiration.—There is a good deal of divergence of opinion with regard to the effects of tropical climate on respiration. According to some, the frequency of respirations is decreased while others hold that it is increased before acclimatization. The consensus of opinion appears to be that the rate is diminished but the depth, as indicated by measurements of the minute volume, is increased. A slightly deeper breathing is more efficient for the individual, economizes energy and, at the same time, the increase in the volume of air breathed cools the system. These changes in the rate and vital capacity are probably of a temporary nature, evident only in the case of the white immigrants to the tropics, and are not apparent in the natives of the tropics. Thus, it has been repeatedly shown that the respiration rate in the native residents of India, Java and the Philippines does not show significant changes as compared with the standards obtained in the cooler countries of the West.

Pulse rate, blood pressure and blood volume.—A slight decrease in the pulse rate and in systolic blood pressure is a very common finding in the tropics. Mills (1936) has shown that people migrating from West Central Europe or Central North America to the tropics nearly always suffer a marked fall in blood pressure within a year or two, even though no debilitating disease or infection has occurred. Probably there is a slight decrease in blood pressure due to lowered vasomotor tone and a general slowing of physiologic activity in the high environmental temperature in the tropics, but the changes are comparatively insignificant. The increase in sweating which is necessary in the tropics must require a constantly increased blood supply to the skin, and has been estimated to be as much as 50 times of the amount in temperate climates. The immediate result, if the total volume remains constant, would mean relative anaemia of the splanchnic region and the vital organs in the abdomen. To counteract such circulatory disturbances there is usually an increase in the total blood volume. Barcroft and his co-workers (1923), in an expedition from England to Peru, found that the blood volume increased as the tropics were entered. The rise in blood volume was accompanied by a fall in haemoglobin indicating that this was a simple dilution effect, blood plasma being drawn into the capillaries from the tissues. These results signify that the organism in the tropics becomes at least temporarily 'wetter' and so is able to sweat more easily and plentifully.

Haematological standards.—The pale complexion of the white races migrating to the tropics has been frequently referred to as an indication of anaemia or 'thinness of blood'. Most authorities are of opinion, however, that a tropical climate *per se* does not produce true anaemia. Several workers in the Dutch East Indies including Eijkman (1924) found that the values for red blood cells and the haemoglobin lay more or less within the same limits for the white sojourner and the native

resident of the tropics. Dhar (1937) in Calcutta studied the normal haematological standards of a large number of Indian women and found that the average values for haemoglobin, red cells, mean diameter of red cells and leucocytes are lower than the average figures reported in the European, American and Japanese literature for the same age groups. Indeed, the normal average haemoglobin value which this worker obtained (11.47 gm.) for Indian women would be considered in Europe and America as bordering on anaemia. Napier and his co-workers (1937) at the School of Tropical Medicine, on the other hand, have not obtained any evidence that the haemoglobin level in the Indians and in the healthy Europeans in India was low. In the healthy male Europeans the haemoglobin was usually about 125 per cent on the Haldane scale (17.2 gm. per 100 c.c. of blood) and seldom below 120 per cent (16.6 gm.). This is much higher than the 'normal' figure usually quoted for Europeans in Great Britain. In two series of normal healthy Indians consisting of 50 and 30 individuals the mean haemoglobin contents were found to be 14.77 gm. and 15.70 gm. respectively. Sokhey (1932) in Bombay got a mean of 15.11 gm. in a large series. These figures are not materially different from the normal figures given for males in Great Britain and, if anything, are slightly higher than the standard figure of 14.5 gm. given by Price-Jones. With regard to the number of red cells, the average figures obtained in the Calcutta series were 5,533,000 and 5,362,000 and the mean of the Bombay series was 5,110,000. These figures are again above the classical 5,000,000. Even if the figure of 5,428,000 given by Price-Jones is considered as the normal mean count, the figures obtained in the Indian series are not much below normal and there is no reason to believe that the size of the red cell differs from that in cooler climates and the colour index volume and saturation indices are all in the neighbourhood of 100.

Most haematologists in the tropics appear to agree that the white blood cells are generally decreased though the change is not very great. As a rule the polynuclears have been found reduced and the Arneeth count shifted to the left. This has been fully confirmed by workers in Iraq and by Dharmendra (1937) in Calcutta. Napier (1935-37) found that the number of leucocytes, if it differed at all, was slightly lower than in temperate climates, but the eosinophile percentage was definitely higher. In 50 normal city-dwelling Indians, who had no heavy helminth infections, the mean eosinophile percentage was nearly 7.0. Not only is the normal eosinophile count of the Indian high, but in disease the eosinophilia tends to attain a very much higher proportion than in the Europeans in temperate climates, e.g., 60 to 80 per cent eosinophilia is not uncommon in asthma and other conditions.

It is not possible, in the present state of our knowledge, to explain the significance of the different haematological responses observed in the tropical races. From the findings of Napier and workers in the West, it seems reasonable to conclude that, far from interfering with the functions of the erythropoietic organs, the tropical climate may actually exert some stimulating action on these organs. The possible bearing of the low average white cell count on the defensive mechanism against disease processes requires further investigation.

Biophysical and biochemical changes in blood.—There is little doubt that there is a more pronounced disturbance of water metabolism and water movement in the tropics than in temperate surroundings. This will naturally be reflected in the water content of the blood. A number of observers have attempted to throw light on this important aspect of tropical adaptation by measurement of blood chloride concentration. Sundstroem (1925) working in Australia found that the blood plasma was more concentrated than normal and richer in chloride content in a hot environment. As the formed elements of the blood actually became richer in water, it was probable that there was a shift of water from plasma to corpuscles. Barbour (1924-25) showed that there is considerable dilution of the blood prior to and accompanying the outbreak of sweat in

hot and humid environment. This hæmodilution may be only temporary as the heat loss through evaporation may reach such proportions that the water in the red cells may be drawn upon to supply the water for perspiration. A slight alkalosis has been reported particularly in persons of sedentary habits which can be removed by water intake and muscular exercise.

The average concentration of serum proteins in the blood of Indians according to Chopra and Mukerji (1931) appears to be slightly lower than the accepted standard figures of Europeans, but the albumin-globulin ratio remains unchanged. The results with regard to non-protein nitrogen content are not conclusive. Since protein intake is likely to be low in the tropics, this will probably be slightly lower than normal. The lipid constituents of the blood including cholesterol have generally shown lower values. Blood sugar apparently is so much affected by the climate though it was generally believed to be high in the tropics. In view of the common belief that the tropical climate tended to produce an increase in blood sugar, it was thought that diabetes was more common in the tropics. The studies of Mills (1930) have shown, however, that diabetes is more common in the temperate climes. Serum calcium is appreciably increased probably as a result of excessive production of vitamin D from ergosterol due to the radiant energy of the tropical sun. Sundstroem reported a reduction of total phosphorus, but the finding has not been confirmed.

EFFECT ON THE NERVOUS SYSTEM

That hot environment actually disturbs the psychological reactions of the individual migrating to the tropics is generally admitted, but it is doubtful if the climate alone is responsible. The climatic element along with a large number of other factors—social hygiene, isolation, sedentary habits, alcohol, etc.—undoubtedly plays a part. There is, however, a physiological basis for the concept that the higher centres may be influenced by a series of stimuli from the peripheral sense organs and there is a theoretical possibility that the nerve cells in the brain might be exhausted or fatigued if the stimuli are of a type to which the nervous system is not ordinarily accustomed. There are many instances where a close correlation of a pathological nervous state can be made with changes in the climatic and meteorological factors. It is, for example, well known in epileptic colonies that the fit incidence rises when the weather is close and sultry, and before and during storms. Migraine is likewise affected by the weather. Victims of chronic pain have a peculiar interest in the weather. Neuralgia, locomotor ataxia, and other painful diseases are always aggravated when it is damp, cold and windy. The weather may influence the course of chronic psychosis and unfavourable conditions may exaggerate pre-existing states of either depression or excitement.

Tropical irritability.—The intense heat and the bright sunlight of the tropics are the two factors which have been most commonly incriminated as agents in weakening the control of the higher centres over the lower and causing the so-called 'tropical irritability and neurasthenia'. Pediatricians in the tropics have often said that in children, memory, initiative and application become bad after the tenth year. It appears however that the measurable physiological disturbances are on the whole not very significant. It has so far not been possible by physiological, psychological and biochemical methods to furnish the desired evidence for altered functions of the nervous system. There may be, however, non-measurable and subtle nervous effects which may be of fundamental importance in the problem of acclimatization. Residents in the tropics are less prone to feel the depressing effects of a continuous high temperature and humidity, and the nervous effects observed among white settlers are conspicuous by their absence in the natives. There is probably no impairment of the higher psychical reactions and memory traces in the former as has been claimed for the white sojourners.

EFFECT ON THE ENDOCRINE SYSTEM AND GROWTH

It has often been observed that the endocrine glands may be disturbed in tropical climes. The association of increased metabolism, high energy level and higher incidence of metabolic diseases in a cooler climate and a sluggish metabolism, a low energy level, decreased resistance to infection and lower incidence of metabolic diseases in a tropical climate are generally recognized, and it is probable that all these factors are ultimately bound up with the question of the activity of the glands of internal secretion.

Thyroid-adrenal apparatus.—Much experimental data, both physiological and pathological, have been collected, indicating that the thyroid-adrenal apparatus may be affected in a hot environment. The defective heat regulation of patients suffering from myxœdema directed the attention of workers to the reaction of thyroid-ectomized animals to changes in temperature. In the thyroid glands of animals reared in a hot environment definite histological evidence of a diminished colloid content has been found. Cramer (1930) adduced evidence to indicate that the activity of this gland is diminished after experimental heat exposure for a certain length of time. So far as the suprarenal gland is concerned, a relationship between this gland and heat regulation has been established by showing that exposure to cold is a powerful stimulus to its functional activity. According to Mills (1929) definite disturbances of body function due to hypofunction of adrenal glands may result from too prolonged and severe moist heat.

That the thyroid-adrenal apparatus is concerned in the heat regulation of the body is borne out by pathological evidence. Lesions of these glands are frequently accompanied by marked disturbance of heat regulation, and conversely disturbances of heat regulation, as in fevers, frequently produce lesions in these glands. High temperatures are known to affect adrenal-ectomized animals more easily, and frequently they die in a temperature which is not serious for the control animals exposed for the same length of time. All these facts indicate that there is a lowered resistance to heat in adrenal insufficiency.

These facts enable us to speculate on the close inter-relationship that exists between heat regulation and the thyroid-adrenal system and which afford a physiological basis for the study of the fascinating problem of the influence of climate on man. It has often been noted that a warm moist climate with little change from day to day is 'relaxing'. This might be the result of a failure to stimulate the thyroid-adrenal apparatus and through it the sympathetic system. Conversely, the cool variable climate, which is associated with increased activity and energy, probably provides a continued stimulus to these endocrine organs and the sympathetic. Mills (1932) considered that it is by whipping up the glands of internal secretion (especially the thyroid, adrenals and pancreas) that the human organism responds to weather stimulation. The same explanation may be applied to the relation between climate and health. Why is the resistance against certain bacterial infections, such as tuberculosis, increased by a suitably cool, dry climate, and by measures such as open air treatment, hydrotherapy and the like? Hitherto, it has been thought that such measures increase the metabolism. An increase in metabolism however can be induced by other means such as muscular exercise, but this is likely to do more harm than good. The answer to the question probably is that those measures are beneficial which stimulate the thyroid-adrenal apparatus without exhausting it and thus strengthen the normal reactions of defence of the organism against bacterial infections. Conversely a warm, moist, monotonous climate weakens resistance against infections, not because it reduces metabolism as many have thought, but on account of the continued absence of stimulus to the thyroid-adrenal and the sympathetic apparatus.

Sex glands.—It has often been stated that girls in tropical and subtropical regions menstruate at a comparatively early age. It is also a well-known fact that

women marry and bear children earlier in warmer countries than in cooler regions. These facts have led to the belief that the tropical climate induces premature sex maturity. There is, however, no direct proof of this as no reliable statistics are available. In India, various ages, ranging mostly between twelve and thirteen years, have been given for the onset of menstruation. These figures are probably derived from observations on the time of motherhood. The mean age for the beginning of menstruation is 15 to 16 years among the negroes on plantations in Jamaica and Barbados. Greater stimulation and earlier maturity of the sex glands have been observed in North American States where the climatic changes are more frequent and more severe throughout the year. Mills and Senior (1930) have collected data to show that human fertility, as indicated by the conception rate, depends on seasonal variations in the temperature. The maximum conception rate is always found when the mean monthly temperature is around 60°F. (15.6°C.). Mean temperatures have 70°F. (21.1°C.) and below 40°F. (4.4°C.) produce a definite depression in conception rate. Ogle (1934) confirmed these observations by experiments on animals and showed that white mice subjected to warm humid environments exhibited a low fertility. These results would indicate a definite depression, instead of a climatic stimulation of the gonadal activity of the females in the hot and humid regions of the tropics.

BASAL METABOLISM IN THE TROPICS

The question of the influence of climate on the basal metabolism of the individual is an important subject and has received considerable attention during the last three or four decades. No satisfactory evaluation of the effect of the climate on metabolism, however, is possible even to-day, in view of the wide divergency in the results recorded. A review of the work carried out in tropical and subtropical regions in different parts of the world shows discordant results. Time will not permit me to make a detailed survey of the evidence presented by different workers but I will refer to the work carried out in India which is typical of that done elsewhere. Mukerjee (1926), experimenting on 15 Bengali medical students, found that the basal metabolic rate was on an average 9 per cent lower than the European standard (Sanborn standard). Sokhey (1927) found that, in 15 out of 21 students, the basal metabolic rate was 10 to 23 per cent lower than that of the Du Bois standard. This was further confirmed by Mason and Benedict (1931) who found the basal metabolism 16.9 per cent below the Haris-Benedict standard or 17.2 per cent below Aub-Du Bois standard. Mukerji and Gupta (1931) showed a decrease in the basal metabolic rate by 13.3 per cent below the Du Bois standard. Krishnan and Vareed (1932) working in Madras found that the basal metabolic rate was 12 per cent lower in man and 16 per cent lower in woman as compared to Du Bois standard. It is not yet agreed whether this lower metabolism is the result of the tropical heat (Rahman, 1936) or is produced by some dietetic or racial factor (Mason and Benedict, 1931). Bose (1934) carried out a large number of observations by the Sanborn technique at the School of Tropical Medicine and came to the conclusion that the basal metabolic rate of healthy normal Indians living mostly on a mixed diet does not differ materially from the accepted standards of Europeans and Americans.

Taking a general view of the whole problem, it would appear that the observations of the majority of the workers who studied metabolism in the tropics are in agreement that there is either a slight decrease or no significant difference in the basal heat production in people living in the tropics as compared with the inhabitants of the cold or temperate regions. It seems inconceivable that such a fundamental factor as basal metabolism should be affected by climate to any great extent any more than the body temperature. A very low or high basal metabolic rate reported in the literature is probably due to uncontrolled observations or possibly some fault in the technique employed.

DIET AND ADAPTATION IN THE TROPICS

Protein and fat requirements.—Among all the demands which the body makes on its environment that for food is of outstanding importance, and it is to-day becoming well recognized that correct nutrition may profoundly affect the well-being and the social value of the individual. Considerable attention has therefore been directed to the adjustment of diet for different deficiency diseases and on the question as to how a well-balanced diet, containing all the proximate principles and other important constituents (vitamins, etc.), could be made available to the masses. Caloric value of foodstuffs, which was at one time the basis of dietetic studies, is for the time being relegated to the background, and comparatively less attention is now being paid to their energy and heat-producing properties.

As pointed out before, the adaptation which man is called upon to make in the tropics is primarily one of heat regulation. The problem of diet is intimately connected with the problems of heat regulation, body temperature and metabolic rate, and any of these factors cannot be considered without reference to the others. Though considerable work has been done on different aspects of dietetics, the question of the suitability or otherwise to the tropical climate of the common foodstuffs available in the tropics is not satisfactorily answered. Nature offers fat and protein in the arctic regions and carbohydrates at the equator, and man in these areas has always accepted them as his staple foods. The old idea that the diet which a race has adopted in a particular region is best suited for its needs has been refuted, in the light of modern research on ill-balanced dietaries and nutritional diseases in those areas. It is not yet clear as to what is the optimum or ideal to be aimed at with a view to effecting a suitable adjustment to the climate.

The proportion of protein, fat and carbohydrate varies considerably in the diets of different races, depending largely on the type of food available and also upon the customs existing in particular localities. The prevailing diet of the masses in the tropics is derived largely from vegetable sources and carbohydrates generally predominate in it. Nearly a century ago, Chevers thought that the Hindu dietary with a very moderate quantity of animal food was the one most suited for a tropical climate. It will be of interest to examine how far the generalization of Chevers is justified.

Biological value of proteins. The protein requirement of the tropical races has been the subject of intensive investigation and research by a large number of workers in India and other tropical countries, but no definite conclusions have yet been drawn. It has been pointed out that in many parts of the world those who consume a diet with high protein content have a better physique and are more virile than others of the same race who, for one reason or another, consume less protein. In the north of Italy, for instance, where the protein consumption is higher, the physique is better than in the south. The same statement has been made about India although here racial differences may have something to do with the differences. McCay said about a quarter of a century ago—'As we pass from the north-west region of the Punjab down the Gangetic plain to the coast of Bengal, there is gradual fall in the stature, body weight, stamina and the efficiency of the people. In accordance with this decline in many characteristics, there is an accompanying gradual fall in the nutritive value of the dietaries'. McCarrison working in South India confirmed the findings of McCay and concluded that there is a chronic protein starvation in the dietary of the Indians. Recent researches by Aykroyd and Wilson in this country have shown that the main deficiency in the diet is the lack of proteins of high biological value and certain salts, and this defect in the dietary, which can be easily corrected with small quantities of milk, is responsible for the malnutrition and consequently the poor physique of the children. On the other hand, the fact cannot be overlooked that the meatless diet of some of the finest soldiers of the Indian army has a low protein content. There is already a considerable volume of opinion that the protein intake in the tropics should be less than

in temperate climates and the Chittenden and Voit standards of protein quota may not be applicable to the Indian dietary. It is well known that protein food, by virtue of its specific dynamic action, generates a good deal of heat. The Eskimos, who live in the arctic zone, consume large quantities of meat, sufficient to raise their metabolism over 50 per cent which is an obvious practical advantage. Such a diet in the tropics would be considered unsatisfactory as it would throw an additional burden on the heat-regulating mechanism which is already over-taxed. From this point of view a low protein vegetarian diet seems logical and advisable in the tropics. Recent researches tend to show that there are a number of important factors which deserve special attention in determining the minimum quantity of protein necessary to preserve nitrogenous equilibrium, *e.g.*, the particular protein the subject is accustomed to take and the ratio of the inorganic bases to inorganic acids available to or formed in the body of the subject. The coefficient of absorption also varies enormously in proteins of animal and vegetable origin. Inhabitants in the tropics usually obtain a large percentage of their protein requirement (70 to 80 per cent) from vegetable sources while Europeans do not draw more than 25 per cent from this source. Vegetable protein is said to have less 'biological' value than animal protein. It is futile to work out an allowance of say 80 gm. of protein per day, if a good portion of it is derived from vegetable sources with poor 'biological' value and it may not be assimilated. Then again, a food may show variation in the absorption of its protein content merely because of various methods of cooking. For instance, *dals* (lentils, commonly used in Indian dietary) if not properly cooked lose a lot of protein value. If they are simply boiled until soft, as is usually done and consumed, about 40 per cent of the protein content is lost from non-absorption. If, on the other hand, they are mashed and cooked with special attention to the temperature and water content, the loss is not so great. This also applies to rice which is the staple article of diet in a large part of India. A diet, theoretically perfect, may still be quite unable to supply the physiological needs of the race for whom it is intended. It is therefore of utmost importance that, in assessing the amount of protein in a diet, its source should be known and the computation for protein requirements made, with special reference to the manner in which it is going to be available for final consumption.

Fat-free dietary.—It is a common experience in the tropics to find that the poorest classes live on an almost fat-free diet. The very small amount of fat that they do eat is also often adulterated. Thus, mustard oil which is consumed by quite a large section of the population in Bengal is often impure and contains adulterants; the palm oil of other tropical dietaries is very variable both in fat and vitamin content. That fat is an important constituent of diet has been long known but that it is also an essential constituent which cannot be replaced entirely, for instance, by carbohydrates was not realized before. Recent researches have forcibly stressed the fact that fats, if completely excluded from the diet, might lead not only to stunted growth but also to the development of various lesions indicative of malnutrition in the body. The fatty acids in fat are probably quite as important as the fat-soluble vitamins. From these considerations, it is logical to conclude that the almost fat-free diet of the Indian races is an important cause of the general and wide-spread malnutrition. From the point of view of adaptation to a tropical environment a diet comparatively poor in fat has obvious advantages. In the colder parts of the world, where harder physical work can be, and often is, performed, a fairly high caloric intake is necessary and this cannot be supplied without including a generous proportion of fat. A caloric intake of a Canadian lumberman of 9,000 calories, for example, could not be consumed as starch without putting too much strain on the demands of the alimentary canal. Fat is much less bulky than cereal foods and, bulk for bulk, is a much richer source of energy and heat. Besides in the tropics an unduly large layer of body

fat—external or internal—is not so necessary as in the cooler regions, which naturally leads to a diminished demand for it in the dietary.

Carbohydrate in the dietary.—Carbohydrates have a definite and important effect on the physiological mechanism of the body. Numerous workers have noted that a change from a fat diet to a starch one involves considerable retention of water and *vice versa*. Some of it is taken up by the stored glycogen and some as extra fluid in the extracellular and probably intracellular fluids. In other words, on a carbohydrate diet, an increased amount of water is available for evaporation and urine secretion in case of necessity. Moreover, carbohydrates are always the first to be metabolized and hence *pari passu* more motile fluid is available while they are being consumed. Experiments on rats on a fat-free diet have shown that these animals consume more water and excrete actually less urine than others with fat in their diet. More fluid appears to be eliminated by the lungs, under such conditions. Further, pulmonary ventilation is greater when carbohydrates are being burnt, owing to a larger output of carbon dioxide per calorie of heat than on a fat diet. This would increase the heat loss by evaporation of water from the lungs. These experiments are suggestive in view of Eijkman's (1924) observations in Java. He found that the Malayan is more economical (physiologically) in his water elimination than the European. Under identical conditions, a European lost 143 gm. of water and a Malayan only 105 gm. of water by insensible perspiration in a given period. Contrary to expectation, the Malayan had also the smaller volume of urine, even though he had received extra water, while the European had been deprived of it during the observation. The European appears to waste water as liquid perspiration which does not therefore perform its physiological function, namely, evaporation and heat loss. The problem therefore is how much of this adaptation is racial and how much of it is due to carbohydrate diet conserving the body fluids. The increased urine elimination of the European may have been due to his greater excretion of nitrogenous products which would be much less in the Malayan with his low protein diet. The Malayan, on the other hand, may consume more salt, which under certain circumstances promotes retention of water.

The considerations set forth above are particularly important if we are to construct a dietary suited to the climatic conditions of the tropics. Some medical men, obsessed by the idea that a good dietary must be rich in protein and fat, have advocated the wholesomeness of the protein-rich European dietary for the tropics, overlooking the fact that whole nations and working classes can develop satisfactorily and lead healthy and mentally productive lives on a diet which is almost equivalent, as far as caloric value is concerned, to the European diet but which is very poor in animal protein. It seems that dietary types like racial patterns cannot be laid down in rigid terms. The dental structure and alimentary canal of man are pre-eminently suited for a mixed diet and he is therefore probably capable of adapting himself to diets varying widely in their compositions. The determination of the minimal animal protein requirements is an interesting subject for future research and it is possible that these depend considerably on climatic considerations.

TROPICAL CLIMATE AND RESISTANCE TO INFECTION

We have so far considered the effect of tropical climate on the individual involving chemical, physiological and psychological reactions. It would be interesting now to examine whether these changes extend to the bacterial flora of the mucous membranes of the throat, respiratory passages, the gastro-intestinal tract and other parts of the body. It is possible that climatic factors not only influence the physiological forces of the organism but also affect the pabulum on which the bacteria vegetate without in any way affecting the bacteria themselves. This brings us to the question of environment and host resistance, the importance of which from the epidemiological point of view cannot be over-rated. It seems logical enough to expect, if

we accept the evidence that has already been presented regarding the alteration of the chemical, hormonal and psychological status of the individual as a result of environmental changes, the localization of bacteria and other micro-organisms in the tissues is favoured by associated changes with altered membrane permeability, vascular changes, metabolic alterations and ionic shifts. If these changes take place in the particular foci, such as the throat and the mucous membrane of the gastrointestinal tract, the host parasite relationship may be altered and clinical disorder may result.

Infections of the gastro-intestinal tract.—There are many recorded experiments as to the effect of temperature and humidity on the resistance to gastro-intestinal infection. Arnold and his colleagues (1927-29) studied in considerable detail the effect of high temperature, especially when associated with high humidity, on the gastro-duodenal bacterial mechanism of the dog. They showed that normal dogs exhibit a self-disinfecting power for ingested bacteria. If a living bacterial emulsion was administered by the mouth, these organisms could not be recovered from the caecum in a viable state. When these dogs were placed in warm rooms (90°-85°F. and humidity 90 per cent) and treated in an identical manner, the bacteria ingested by mouth were passed on to the caecum in a viable state, showing that the heat and humidity caused an interference with the bactericidal power of the dog. Again bacteria injected into the ventrally fixed duodenum of dogs placed in warm rooms soon appeared in the caecum in large numbers. The same animals, handled in a like manner at ordinary room temperature, destroyed the bacteria before they reached the caecum. Since in these experiments gastric acidity was excluded, one must assume that there was some other factor besides gastric acidity, or, in other words, that the humid heat caused a change in the bacteriolytic action of the intestinal mucosa. In mice infected *per os* with the same dose of *Salmonella enteritidis* the fatality at a high temperature and high humidity was almost three times what it would be at the same temperature but with low relative humidity.

These experiments show that high temperature associated with high humidity favoured the passage of infecting organisms across the gastro-duodenal barrier and increased the permeability of the intestine so that the bacteria could pass into the lymphatics, and finally reduced the defence of the animal to such an extent that the severity of the infection was enhanced. The fact should not be lost sight of that these experiments dealt with sudden changes of temperature and humidity. Had the experiments been conducted on animals acclimatized to a tropical climate, the results might have been different.

In attempting to correlate the experimental findings with clinical data, we are confronted with certain difficulties. It is known that enteric infections, dysenteries, diarrhoea, and colitis increase during the spring and summer months and diminish during the winter. This increase, which is often sharp and sudden, is partly ascribable to the sudden rise in the external temperature which probably inhibits the gastric secretions and allows either infectious organisms or irritating toxic substances to pass more readily into the lower intestinal tract. Furthermore, it would appear that at a high humid temperature the intestinal tract is also more sensitive to the irritating substances produced by the normal intestinal flora. Mills (1928) in China called attention to gastro-intestinal disturbances, associated with nausea and vomiting, following a sudden elevation in temperature and humidity. Similar effects have often been observed in India and Egypt. A sudden change to a high, humid temperature may therefore facilitate infection, or give rise to non-specific irritation. It is possible that there are certain other factors such as seasonal changes in the vitamin content of food-stuffs which are responsible for the rise and fall of resistance.

Goldwasser and Kligler (1930) studied the character of the intestinal flora of normal individuals during different months of the year under the influence of the usual diet. The number of bacteria excreted by a

normal person was variable. During winter, the number of bacteria was relatively high, and cocci and anaerobic spore formers predominated, while in spring there was a transformation with a fall in the bacterial content with the coli group preponderating and cocci and spore-formers diminishing. This indicates that, associated with the sudden rise in temperature, there are changes in the intestinal tract favouring the development of saprophytic and pathogenic members of the colon-typhoid group. The accumulated data go to show, therefore, a seasonal flux in the condition of the intestinal tract of man, while the experimental results obtained with animals show to a large extent that corresponding changes are induced in them by a change from an environment with a high to one of low cooling power.

Evidence of significant changes in the physiological condition of the nose and nasopharynx in response to changes in temperature and humidity has been produced and it may well be that some of the changes are associated with a lowering of local resistance and a predisposition to cold and other respiratory infections. Cock and Mills (1932) investigated the effect of atmospheric conditions on the upper respiratory tract and found evidence to indicate that it was not only the bacteria which were responsible for the catarrhal inflammation in the respiratory tract, but environmental factors such as seasonal alterations in temperature and humidity were also important accessory factors. External temperature and humidity were important controlling factors in the incidence and death rate of lobar pneumonia. In diseases like asthma, many workers in the field have recognized the influence of climatic variations and have more than once shown the association of climatic fluctuation with asthmatic attacks. Evidence has also accumulated which shows the seasonal fluctuations of streptococci in the throat observations on 4,857 throat cultures from 123 rheumatic children and have shown conclusively the close relationship of the pharyngeal flora with seasonal variations and the incidence of rheumatic attacks. Sharp and John (1937) have shown that carriage of summer streptococci is at a low level during the States of America tends to prevent or mitigate an attack of rheumatism. More information however is needed to prove direct correlation between environmental features and naturally occurring infections of the respiratory passages.

Radiation and resistance to infection.—It has been suggested that ultra-violet irradiation of the body, which is naturally obtainable in the tropics, has the power of increasing resistance to infections. A number of workers have demonstrated a temporary increase in the bactericidal power of the blood as the result of exposure to ultra-violet rays. This view is, however, not universally accepted. A careful study of the frequency of colds among irradiated and unirradiated groups of volunteers at Johns Hopkins Hospital has definitely shown that resistance to infection is not altered by irradiation. Similar results were obtained with rabbits injected with *Pasteurella leptiseptica*.

Immunity reactions.—I do not propose here to enter into the field of immunity reactions and immune bodies in relationship to climatic changes. It is certain that the titre of immune bodies will change with the alterations in the physico-chemical status of the blood. The Report of the New York State Commission on Ventilation (1923) states that rabbits maintained at a temperature of 86°F. (30°C.) showed distinctly delayed formation of hemolysins and reduced agglutinating power, as compared with control animals kept at 68°F. (20°C.). It has been recently shown that in rabbits, heated so that their body temperature is raised to above 104°F. (40°C.), agglutinins and bacteriolytic substances are produced in greater quantities than in control animals kept at room temperature. These preliminary studies indicate interesting inter-relationships and open up a new field of investigation.

Allergic manifestations.—A few words may be said about hypersensitiveness and allergy in the tropics as the phenomenon is closely associated with resistance to infection. The Indian tribes of America suffered much less from allergic diseases and were much less susceptible to experimental serum disease than the white races. Acton and Dharmendra (1933) pointed out the rarity of asthma of allergic origin amongst Indians. The reason for this lower incidence is not known and will remain unanswered until the true nature of allergy is known. There is evidence, both experimental and clinical, that hypo-adrenia plays an important rôle in the production of allergy. It has also been claimed that slight changes in the biochemical make-up of the body might give rise to profound changes in the reactions to foreign bodies and external stimuli. It has been shown, for example, that a shift of the hydrogen-ion concentration to the alkaline side greatly increases sensitiveness in certain tissues. I have already indicated that hypo-adrenia might well be brought about as a result of tropical heat. If this hypothesis is accepted, a higher incidence of allergy in the tropics would be expected. Apparently such is not the case. This question must be thoroughly studied before any satisfactory explanation can be offered.

CONCLUDING REMARKS

From the survey of the effects produced by tropical environments on the physiology of the individual, certain points emerge which are worthy of further consideration and discussion. The idea that living bodies receive modifying impressions, both as regards form and quality, from the physiological environment is of ancient origin and may be said to be definitely established by the experimental physiological data now available. There are however many lacunæ in our knowledge of the physiology of the external environment which need filling so that we may present a connected account of all these alterations in the functions of the human organism. The human organism (the microcosmos) swings in a definite rhythm with the macrocosmos (atmospheric environment). In the interplay of the meteorological rhythm with the biological rhythm of the individual, there may be synchronization, amplification, summation, or negation of effects, depending on the type and reactivity of the individual. It is conceivable, for example, that a long, thin, flaccid individual will react to an environmental feature such as atmospheric temperature, differently from a florid, stocky and strong type of individual. This brings us to the important question of 'constitution' and shows how the question of normality may be inter-related ultimately to the constitutional types. For all practical purposes, however, it is not necessary to consider such individual fluctuations and peculiarities, as many of these variations are smoothed over and neutralized when larger groups are considered. It is therefore to standardize physiological data in terms of 'normal' and 'normal ranges' that we consider groups, and not individuals.

There is great need for determining such physiological normals in the tropics. Even in such simple matters as body temperature, blood pressure, etc., the findings are not always in accord. The question of a normal standard must necessarily be one for revision in the light of additional data and more exact technique. The differences of technique alone account for much of the difficulty in correlating earlier results on blood chemistry and blood pressure. When we are in a position to compare alterations produced in response to tropical environment, in terms of 'normals' fixed in the tropics on 'tropical' individuals, we will not only be able to understand and explain their significance more fully, we may also be able to find out the optimum environmental conditions necessary in the tropics for the maximum development of physical and mental vigour. That environmental factors determine to a great extent the progress of mankind, Huntington has shown, and many of his conclusions have been confirmed by Mills.

The immediate effects of tropical heat and humidity on the inhabitants of cooler climates are known. Most

of the physiological measurements have been recorded either on white races migrating to the tropics or at best on white settlers in the tropics. But these data cannot be used satisfactorily to explain how a native of the tropical climate would react to such variations. These records of altered physiological manifestations are no doubt useful indications of the type of variations to be expected, but any comparisons with the European figures as the standard will naturally be of doubtful value. Creditable attempts have been made by pioneer workers in the Philippines and Australia to supplement the information obtained on human races, by carefully controlled experiments on animals in artificially produced tropical environments. These animal experiments have supplied a large amount of useful data but these are also subject to the same criticism. The experiments were conducted for specified periods and though the results look quite conclusive as far as they go, they throw no light on how animals accustomed to tropical environments for generations would react to climatic changes. There is much scope for work of this kind in India with local strains of animals reared under conditions peculiar to the country.

The question of basal metabolism and the inter-related problems of optimum diet in the tropics needs further investigation even though the available data are by no means meagre. There seems to be some evidence to show that metabolism in the tropics is slightly lower than in cooler climates. As this observation fits in remarkably well with the known physiological facts regarding heat regulation in the tropics, and the diet in the tropics is predominantly rich in carbohydrates and poor in fats and proteins, European investigators are prone to lean to this view. Work in the Calcutta School of Tropical Medicine, however, has shown that there is hardly any difference in the basal metabolic rate in apparently healthy Indians (Bengalis) subsisting on an ordinary mixed diet. It is important, therefore, to re-investigate the problem and to see whether any racial factor is involved in it. Intimately associated with the question of basal metabolism is the question of the functional activity of the endocrines. There is some evidence to show that tropical environments depress the thyroid-adrenal apparatus as well as the gonads, and the sluggish metabolism, the lower energy rate, the earlier onset of the menopause and the supposed lowering of host resistance are only expressions of this endocrine dysfunction and inadequacy. Here lies an aspect of physiology which should attract young scientists. While some observations by histopathological and histochemical methods on the colloid content of the thyroid gland and the presence or absence of 'granules' in the cortex and medulla of the suprarenals have been recorded as evidence of their altered function, and while quite a large volume of work indicating the active participation of the supra-renal glands in the process of 'chilling' has emanated from the laboratories of Prof. Cannon of the Harvard University, there is as yet no definite and direct proof of this endocrine insufficiency or dysfunction under tropical environments. No satisfactory method exists for estimating the amount of adrenalin in the circulating blood and body fluids. If such a method can be devised and the technique perfected, it will be a distinct advance in the study of the activity of the endocrine functions in individuals living under different climatic environments, and in correlating this activity with increased or decreased metabolism, increased or decreased resistance to infections, increased or decreased somatic reflexes and psychological status of individuals. It has been reported that the incidence of metabolic diseases, viz, diabetes, exophthalmic goitre, and Addison's disease, pernicious anemia, angina pectoris, chronic nephritis, etc., is lower in the tropics than in the temperate zones, while, on the other hand, the infectious diseases generally are more common. It is also a general belief that sexual maturity is gained earlier in the tropics than in cooler climates. Recent researches however tend to indicate that the reverse is probably true. Much useful work could be done in this connection in India. It is

probable that the final answer to these and to many such conflicting hypotheses will be found through a study of the endocrine inter-relationships. In presenting this subject, I realize more than anybody else the complexities of the task and the limits of the undertaking that I have set upon myself. On going through the literature on the subject, one is forcibly struck with the extremes of opinion held and the disparities in the observed and recorded facts regarding the various responses of the body to climatic changes. The reason for these differences is not far to seek. The study of this aspect of physiology presents inherent difficulties, as here, unlike that of other problems, one has to analyse carefully the innumerable possibilities entailed by the inter-action of two highly dynamic systems, viz, the atmospheric environment with its constant fluctuations and 'pulsations' due to cyclonic circulation and temperature changes of the incident solar energy, on the one hand, and the human individual, that integrated cell mass in a state of dynamic equilibrium with his internal environment, on the other. The study of the physiological basis of the effect of climate on the individual shows that he is fashioning his own evolution by struggling to adapt himself to his climatic environment. This adjustment is brought about by three major components of the autonomic

apparatus—chemical, hormonal and nervous. We have to study all these systems in all their various phases and ramifications, correlate all the disjointed observations in logical sequence and fit them into a perfect mosaic. Only then can we hope to project a picture, complete in its details, of the phenomena of biological adaptation of the organism to its environment, as exemplified in the process of acclimatization—individual or racial—of human beings in the tropics. In modern medicine and physiology, a consideration of the environmental influence has been relegated to the background for it has been thought that all acute infectious processes and normal physiological events run a comparatively steady course, uninfluenced by environmental factors. Enough scientific evidence is now available, some of which has been discussed already, that when these important forces to be reckoned with and that when these are studied in greater detail, particularly with reference to the changes that they might produce in the human organism, a new branch of physiology may be developed in this country. The material is in abundance; but it needs the sickle of properly organized and directed research to garner a harvest which will be of the greatest value to us in India as well as to the world at large.

Medical News

LADY LINLITHGOW INAUGURATES CAMPAIGN AGAINST TUBERCULOSIS

King-Emperor's personal interest

UNDER the auspices of His Majesty the King-Emperor, an appeal on behalf of a fund to combat tuberculosis in India was launched on 1st December by Her Excellency the Marchioness of Linlithgow. To be known as the King-Emperor's Fund, the project will commemorate in India the accession to the Throne of His Majesty the King-Emperor, who has graciously consented to its inauguration. His Excellency the Viceroy is in whole-hearted sympathy with the proposal, which is also obtaining the support of Governors of the Provinces, Ruling Princes of the Indian States, Members of the Viceroy's Executive Council, the Presidents of the Council of State and the Legislative Assembly, and the Chief Justice and Judges of the Federal Court of India. The purpose of the fund will be the establishment and financing of an All-India Association for the prevention and treatment of tuberculosis. The Association will consist of a central organization at the headquarters of the Government of India, supported by Provincial and possibly State organizations, which will be expected to affiliate with the Central Body. A uniform policy will be applied to the circumstances of the various localities in which tuberculosis prevails.

ATTACK FROM FRESH ANGLE

His Majesty the King-Emperor has taken a personal interest in the problem of tuberculosis in India. Her Excellency Lady Linlithgow has been intimately associated in recent years with all developments in tuberculosis work, more particularly with the work of the Papworth Settlement in England where, in addition to hospitals for men and women patients, an elaborate after-care scheme has been developed with outstanding success.

No one who knows India doubts that of all the diseases which afflict the country, tuberculosis is at once one of the most deadly and the most insidious and the one which most needs attack from a fresh angle. The new organization will not supplant but expand the existing tuberculosis organizations, which are supported by the King George V Thanksgiving (Anti-Tuberculosis) Fund, and will augment preventive and health work sponsored by central and provincial public

Of the money raised it is proposed that 95 per cent should be retained for local purposes, the remainder being earmarked for expenditure on central activities. In view of the great need which this appeal is to meet, it is hoped that a very substantial sum will be raised in response to it. Several handsome donations have already been received or promised.

Her Excellency's appeal

The following is the text of the appeal issued by Her Excellency:—

'I have for a long time been deeply interested in the work which is carried out in England to combat tuberculosis, and, turning my mind to the same subject when I came to India, I have found that here also this terrible disease has been working incalculable harm. From inquiries which I have made I am satisfied that of all the evils which afflict India and which charitable endeavour, strengthened by adequate resources and properly directed, can help to mitigate, tuberculosis is at once the most deadly and one which most needs attention in a fresh aspect. Everyone who has experience of the ravages of tuberculosis must know how dreadful a danger it is to the life, the happiness, and the spirit of the community. I believe that the public conscience in almost every class of society is already greatly stirred by the menace of tuberculosis, and I feel that it would be difficult to render the people of India a better service than that of trying to protect them against this terrible scourge. I know too that the disease is primarily an urban one; but the extent of its increase in recent years in rural areas shows how important it is to extend preventive measures to those areas also. I have therefore decided to appeal to the whole of India for the collection of money on as large a scale as possible to finance a determined and continuing campaign against the spread of the disease.'

HIS MAJESTY'S APPROVAL

'I am happy in being able to announce that His Majesty the King-Emperor has approved my plan and, by way of showing his direct and immediate sympathy with it, has graciously consented to the Fund which I propose to raise being named the King-Emperor's Fund. All will agree that there could be no more fitting and beneficent memorial of His Gracious Majesty's Accession than a Fund such as this. His Majesty's interest in the scheme is close and personal and he

asked to be kept informed of the progress of my undertaking.

'If I am as successful as I hope to be, it is intended to found an Anti-Tuberculosis Association for India, consisting of a Central Body supported by Provincial and State organizations, which would be expected to affiliate themselves to the Central Body, and to apply a uniform policy to the circumstances of the different localities in which tuberculosis prevails. The expenditure in the Provinces and States would be mainly on the maintenance of clinics and where possible on sanatoria and after-care settlements, while the expenditure at headquarters, directed by experts and representatives of the affiliated organizations, would be on research, the providing of technical advice and general co-ordination of effort, and on a central model clinic in Delhi.

CO-OPERATION NECESSARY FOR SUCCESS

'But as the most effective and really concrete work falls to be done in the Provinces and States, I propose that of the monies raised in the Provinces and States in answer to this appeal as much as 95 per cent should be returned for local expenditure, and the remaining 5 per cent, together with any subscriptions that may be voluntarily earmarked by the donors for expenditure on central activities, should be retained by the Central organization.

'The people of India are well known for their charity and their benevolence to suffering humanity. I feel confident therefore that my appeal will be received with the sympathy it surely deserves. It is a most earnest and sincere appeal. I myself will spare no effort to prosecute it and at all times to aid in the fight against tuberculosis to the best of my power. But success demands the practical co-operation of the people of India themselves; and I hope with all my heart that I will have this in full measure.

'I hope that everyone in India, rich and poor, will contribute according to their means—much or little—to this great cause, grasping a noble opportunity of united effort to oppose a great evil in India and to promote the highest welfare of her people'.

H. E. the Viceroy's call to action

In a message accompanying the appeal His Excellency the Viceroy said:—

'The appeal which Lady Linlithgow is making for the King-Emperor's Fund for the prevention and treatment of tuberculosis in India has my warmest and heartiest support.

'I know only too well the ravages which tuberculosis has caused and is causing in India, and the threat which it constitutes to the health and the happiness of her peoples and the development of this great country cannot be exaggerated.

'From the enquiries I have made in many quarters, and from my conversations with persons well acquainted with the preventive measures which are being taken, I am fully alive to the importance which Indian public opinion attaches to early action to safeguard the position.

'Of the sums now to be collected 95 per cent will be attributed for disposal to the Provinces and the States in which they have been collected, and I am confident that public spirited individuals in provinces and States alike will seize this opportunity of showing by their generous contributions and the importance which they attach to safeguarding the area with which they are most closely associated, and that the response to the appeal which is now being made under the gracious patronage of His Majesty the King-Emperor will be outstanding in character'.

KING-EMPEROR'S DONATION

When the list of donations to the Tuberculosis Fund was opened on 1st December, it was headed by the King-Emperor and included notable contributions from

all over India. The list of contributions on that date was as follows:—

Their Imperial Majesties.		
His Majesty the King-Emperor	£750	} £1,000
Her Majesty the Queen-Empress	£250	
Their Excellencies the Viceroy and Lady Linlithgow		
His Exalted Highness the Nizam of Hyderabad	..	Rs. 10,000
His Highness the Maharaja and the Government of Jodhpur	..	Rs. 5 lakhs
His Highness the Maharaja of Bikaner	..	Rs. 2½ lakhs
His Highness the Maharaja of Indore	..	Rs. 2¼ lakhs
	..	Rs. 2 lakhs

Donations of Rs. 1 lakh each were received from His Highness the Nawab of Bhawalpur, the Council of Regency, Nabha State, and His Highness the Maharaja of Morvi, Rs. 75,000 from His Highness the Maharaja of Patiala and Rs. 30,000 from the Chamba Darbar.

Formation of local committees

Committees are to be formed as soon as possible in all Provinces, Administration and States to raise subscriptions on behalf of the appeal made by Her Excellency.

These committees will announce the names of those authorized by them to receive money on their behalf.

Donations to the Fund may be paid either:

To the representatives of these committees; or,

In a place where there is no branch of the Imperial Bank, into any Government treasury or sub-treasury in India, or

Into any branch of the Imperial Bank of India, for credit to the account, when opened, of the committee of the area concerned.

Donations may also be sent direct to the Honorary Treasurer (Mr. A. C. Badenoch, C.S.I., C.I.E., I.C.S.) or the Secretary (Lieut.-Col. R. O. Chamier, C.I.E.) of the appeal at the Viceroy's House, New Delhi.

Donations received direct in New Delhi, unless expressly designated as for the centre, will be allocated to the Province, Administration or State from which they emanate.

Lists of donations will be issued periodically by the local committees in Provinces, Administrations and States and by the headquarters of the Fund at New Delhi in respect of sums received by each.

SCIENCE CONGRESS JUBILEE

H. E. the Viceroy's opening speech

HIS EXCELLENCY THE VICEEROY opened the Silver Jubilee Session of the Indian Science Congress at Calcutta on 3rd January in the presence of a distinguished gathering of British and Indian scientists and prominent foreign visitors.

A delegation of the British Association, who are visiting India for the Congress, formed a large part of the audience which heard the Viceroy's address and the inaugural speech delivered by Sir James Jeans, leader of the British delegation.

Amongst British physicians present were Dr. E. P. Poulton, Physician to Guy's Hospital, London, Dr. E. Mapother, of the Maudsley Mental Hospital, London, Professor F. A. E. Crew, Professor and Director of the Institute of Animal Genetics in the University of Edinburgh, and Professor P. A. Buxton, Professor of Medical Entomology, London School of Hygiene and Tropical Medicine.

His Excellency congratulated the Indian Science Congress on the successful completion of its first 25 years. He felt it had been a happy decision to make the special character of the session the extension of invitations to representatives of the British Association and to scientists of other countries to join the discussions and celebrations.

His Excellency also commented on the appropriate choice in selecting Calcutta as the venue of the Congress. The Indian Science Congress owed a deep debt of gratitude to the Royal Asiatic Society of Bengal which had been, in fact, foster-parent to the Congress in its early days.

The Viceroy referred to the death of the late Lord Rutherford, who was to have presided, and of the late Sir Jagdish Bose, and extended a special welcome to the President of the Congress, Sir James Jeans, to whose work in popularizing knowledge of astronomy, His Excellency paid tribute.

INDIANS' VENTURES

In the course of his speech, His Excellency said:—
'Since the early seventies of the last century, young Indians began to interest themselves in science and to proceed abroad, on what then constituted brave ventures for many of them, to learn science.

'With the consequent increasing scientific activities in India the want was felt of an institution which would organize meetings of workers in different branches of science; to further the cause of science and to bring its needs and services to the notice of those who are in a position to help in its objectives.

'The aims with which the Indian Science Congress Association was founded were threefold. First, to encourage research and to publish the results amongst scientific workers in India; secondly, to give opportunities for personal intercourse and scientific companionship; thirdly, to promote public interest in science. These aims have been magnificently fulfilled.

'At the first meeting of the Association there were five sections, chemistry, physics, geology, botany and ethnology. The membership was 109 and 31 papers were read.

'At this year's conference there are 13 sections, a membership of more than 1,600 and 800 papers have been notified for reading. There are to be 22 discussions within individual sections and 10 joint discussions on programmes which concern more than one section.

INDIA'S SCIENTISTS

'India to-day can claim not a few scientists, the originality of whose contributions in different branches of science has won for them international recognition, and I feel that the presence of so many eminent scientists from abroad sets the seal of international recognition upon the position to which science in India has now attained.

'The future of science in India is full of encouragement. India has demonstrated that she possesses men of capacity with the will to labour, and if we have workers equipped to take their place amongst those who to-day in every continent are engaged, whether in pure or in applied science, in advancing the frontiers of human knowledge, it is evident that India affords limitless opportunities for the harnessing of that knowledge for the betterment of mankind.

'By universal accord the first and foremost object of our endeavour in the material field must be to better the lot of the agricultural population, to raise the standard of living of the cultivator.

FASCINATING CHALLENGE

'I can imagine no more fascinating challenge to young scientists in this country than the employment of their brains and the application of the latest scientific knowledge to the attempt to solve the manifold problems of material advancement that confront us on every side.

'But encouraging though the prospect may be in theory, India is faced with the same practical difficulties that other countries experience of making provision for research and scientific activities.

GOVERNMENT'S BURDEN

'But the financial burden of this research falls either immediately or in the long run on Government. Research institutions are almost exclusively maintained either by the Central or Provincial Governments. The work of the universities is substantially subsidized by

the Governments of the Provinces in which they are situated.

'It is to my mind an unsatisfactory state of affairs that Government, with the manifold calls on its financial resources, should have to bear the main burden also in this respect.

'The scope for scientific research, whether pure or applied, is practically unlimited and no small obligation exists on private munificence to supplement what Governments are now doing in work which Government has for so long so anxiously supported, and to which it continues to-day directly or indirectly to contribute on no mean scale.

SCIENCE'S OPPORTUNITIES

'The opportunities of science are great—the field remaining to be explored immense. I am confident that in asking for a still further development of the substantial assistance which over so many years has been afforded by generous donors, I can rely on a response comparable in some degree with the needs to be met.

'The presence of this distinguished gathering constitutes a manifestation of the interest taken by the intellectual world of the West in the trend of developments in India. Interest from such a source is of inestimable value to India at the present time. It will, I feel, continue to be of value in the future.

'India is in a transitional stage; she is on the threshold of a new era. We may anticipate that the recent political reforms will inevitably find their reflection in an increased determination among Indians that India should continue in increasing degree to make her own individual contribution to world history and world concepts.

'What will be the nature of that contribution and what its scale, it is difficult to foresee clearly at this period.

'The history of Indian civilization goes further back than any history of Western countries. The great name of India has throughout that long history at all times been associated with religion, with mysticism, with philosophy and with the arts.

'Throughout the centuries her economy has been, as indeed it is likely to continue to be, fundamentally agricultural, with the simple patient, methodical and thrifty life for the people which that implies.

CHALLENGE TO ACCEPTED THOUGHT

'With the march of the years there has come the inevitable impact of the West and India to-day is engaged in welding on to her old structures the newer political and economic forms of the West, in finding in her intellectual life a place for the discoveries of science and practice.

'This is a time, therefore, when interest, understanding and sympathy are vital from those especially who are leaders in science and in those kindred activities which have been so dominant a characteristic of Western development in recent years.

'When talking of civilizations it is difficult to dissociate a scientist from the background against which he works and from the effect of his work on the development of his times. The scientist has his place not only in the world of science but in society as a whole.

'The backgrounds against which scientists in India and the West pursue their activities are vastly different and the possible effects on society from the impact of their discoveries on everyday life must inevitably vary.

INDIA'S SPIRITUALITY GIVES HOPE

'But that difference in no way diminishes the value to us in India of the informed interest, advice and wide and varied experience of those who have seen the possibilities and the limitations of scientific activity in other spheres.

'Your knowledge, your experience, your very aloofness from the Indian background will impart a special value to any analysis of the problems which confront us here, and to any suggestions, which, in the light of your

deliberations, you may feel able to advance as to the directions in which investigation and examination can most fruitfully be pursued.

'But the value of the visit will not be felt on one side only.

'Even the most enthusiastic believer in Western civilization must feel to-day a certain despondency at the apparent failure of the West to dominate its scientific discoveries and to evolve a form of society in which material progress and spiritual freedom march comfortably together.

'Perhaps the West will find in India's more general emphasis on simplicity and the ultimate spirituality of things a more positive example of the truths which the most advanced minds of the West are now discovering.

'Is it too much to hope that you, gentlemen, will be a channel through which India will make in increasing degree that contribution to Western and to world thought which those of us who know and love India are confident that she can make in so full a degree?'

THE INDIAN HONOURS LIST

1ST JANUARY, 1938

THE following are the names of medical men and others, associated with medical institutions, in the Indian Honours List of date 1st January, 1938. We offer them our congratulations:

K.C.I.E.

Major-General E. A. Walker, C.B., I.M.S., lately Director of Medical Services in India, Army Headquarters.

C.I.E.

Colonel P. S. Mills, I.M.S., Surgeon-General with the Government of Bengal.

Lieutenant-Colonel F. A. Barker, O.B.E., I.M.S., Inspector-General of Prisons, Punjab.

Lieutenant-Colonel R. V. Martin, I.M.S., Officiating Inspector-General of Prisons, Bombay.

Lieutenant-Colonel G. T. Burke, I.M.S. (Retd.), lately Secretary, Medical Council of India.

O.B.E.

Miss Louie Brooks, Honorary Secretary, United Kingdom Branch, Lady Dufferin Fund Association.

Khan Bahadur Ahmad Bakhsh, I.S.O., Superintendent, Prince of Wales Hospital, Bhopal, Central India.

Captain P. W. Barnard, Director, Barnard Institute of Radiology, Madras.

M.B.E.

A. C. W. Dessa, I.M.D., X-Ray Department, Irwin Hospital, Delhi.

W. S. Martin, I.M.D., Civil Surgeon, Coonoor, The Nilgiris, Madras.

Rai Bahadur Pitambar Pant, Civil Surgeon, Etawah, United Provinces.

W. P. Todhunter, Officer Supervisor, Office of the Director of Medical Services in India, Army Headquarters.

Kaisar-i-Hind Medal (First Class)

Miss Sarah Janneson Rankin, Medical Officer, St. Margaret's Hospital for Women and Children, Poona City, Bombay.

Mrs. Mary Hilda Youle Remfry (wife of Mr. Justice C. O. Remfry, now retired), Bengal.

Major J. M. Pereira, M.B.E., I.M.D. (Retd.), Superintendent, Patna Medical College Hospital, Bihar.

Mr. H. V. Tilak, Medical Practitioner, Bombay.

Kaisar-i-Hind Medal (Second Class)

Miss Nancy Ethel Bleakly, Medical Superintendent of the Church of England Zenana Mission at Ratanpur, Bengal.

Mrs. Violet Brown, Officiating Matron, Patna Medical College Hospital, Bihar.

Mrs. Primrose Carman, Matron, Thomason Hospital, Agra, United Provinces.

Mrs. Annie Laura Edmunds, Honorary Worker at the Hiranpur Mission Hospital, Santal Parganas, Bihar.

Miss Madeline Rosa Shearburn, M.B.E., Doctor-in-charge, Zenana Mission Hospital, Tank, North-West Frontier Province.

Mr. Shankar Rao Yado Rao Deshmukh, Honorary Secretary of the Red Cross Society, Central Provinces and Berar Branch, Nagpur.

Rai Sahib Nilmani Pal, Professor of Surgery, Prince of Wales Medical College, Patna, Bihar.

Mr. N. Subramanyam, Medical Officer of Health, Sholapur Municipality, Bombay.

Kaisar-i-Hind Medal (Third Class)

Mrs. Florence Mabel Tennent, Nurse, Anglo-Indian Child Welfare Centre, Royapettah, Madras.

Miss Salisabeth Tirki, Doctor-in-charge of the Lady Dufferin Hospital, Bhagalpur, Bihar.

Mr. B. W. Advani, Honorary Physician, Civil Hospital, Karachi, Sind.

Sardar Sahib Jemadar J. S. Gill, I.M.D.

Mr. P. Joseph, Medical Officer, Afghan Mission Hospital, Peshawar, North-West Frontier Province.

M. R. Ry. G. S. Rao, Health Inspector, Anti-Malarial Operations, Vizagapatam Agency, Madras.

Rai Bahadur

Mr. R. N. Sewal, Provincial Medical Service, Civil Surgeon, Muttra, United Provinces.

Rai Sahib S. K. Sen, Civil Surgeon, Purnea, Bihar.

Rai Sahib G. C. Das, Honorary Assistant Surgeon, Imphal, Manipur, Assam.

Rao Bahadur

M. R. Ry. R. A. D. G. Avargal, Retired Civil Surgeon, Madras.

M. R. Ry. C. S. G. P. Avargal, Health Officer, Corporation of Madras, Madras.

Mr. V. R. Phadke, Principal, Bombay Veterinary College, and Officiating Director of Veterinary Services, Bombay.

Sardar Sahib

Sardar J. Singh, District Medical Officer of Health, Montgomery, Punjab.

Mr. L. Singh, Sub-Assistant Surgeon, First Class, Selection Grade, Civil Hospital, Pyu, Burma.

Khan Sahib

Mr. R. A. Shaikh, Bombay Subordinate Medical Service, Officer-in-sub-charge, Civil Hospital, Dhulia, West Khandesh, Bombay.

Mr. K. K. Elahi, Provincial Veterinary Service, Class I, Professor of Parasitology, Punjab Veterinary College, Lahore, Punjab.

Munshi A. S. Khan, Assistant Civil Surgeon, Peshawar, North-West Frontier Province.

Mr. G. Rasool, I.S.O., Superintendent, Medical Branch, Headquarters, Peshawar District.

Rai Sahib

Pandit A. D. Bhandari, Provincial Subordinate Medical Service, In sub-charge, Balrampur Hospital, Lucknow, United Provinces.

Lala G. Kapur, Vice-Principal and Lecturer on Pharmacology and Therapeutics, Medical School, Amritsar, Punjab.

Babu Shashi Bhushan Dutta, Civil Surgeon, Bhagalpur, Bihar.

Babu Nilendra Nath Chatterji, Assistant Medical Officer, South Bihar Sugar Mills, Ltd., Bihta, Patna District, Bihar.

Babu Radha Prasanna Ghosh, Private Medical Practitioner, Samastipur, Bihar.

Babu Kashinath Misra, Teacher of Surgery, Orissa Medical School, and Deputy Superintendent, Cuttack General Hospital, Orissa.

Rao Sahib

M. R. Ry. C. N. V. R. Avargal, District Health Officer, Madras.

M. R. Ry. K. G. M. Avargal, Sub-Assistant Surgeon (Retd.), Madras.

Mr. C. G. Antani, Subordinate Medical Service, West Hospital, Rajkot, States of Western India.

ESTIMATED WORLD REQUIREMENTS OF DANGEROUS DRUGS IN 1938

THE statement issued by the supervisory body under Article 5 of the Drugs Limitation Convention of 1931 giving the estimated world requirements of dangerous drugs in 1938 has just been published by the League of Nations.

The statement makes provision for the dangerous drugs requirements of every country and territory in the world. The total number of separate administrative units (*i.e.*, countries, colonies, dependencies, protectorates, etc.), for which estimates are given in the document, is 179. In preparing its statement, the supervisory body had to examine estimates for 63 countries and 104 territories. In addition, in accordance with the obligation imposed upon it under the Convention, it established estimates for ten countries and two territories, for which estimates had not been furnished by the Governments concerned.

The publication of this statement comes in the fifth year of the existence of the supervisory body, which took the opportunity during its two sessions this year of reviewing the working of the system of estimates and of international control created by the Drugs Limitation Convention. Four years' practical experience of this system has proved its efficiency. A close co-operation has been built up with practically every Government in the world. In this field of its technical work the League has realized in a very complete measure the principle of universality.

In order to carry out the task imposed by the Convention of securing universal application, the supervisory body has endeavoured from the outset to elaborate principles and procedures capable of being applied with the same degree of efficiency not only in large industrialized States with an elaborate administrative machinery, but also in small countries and territories—even including small islands like those of the Pacific with a few thousand inhabitants and a rudimentary legislative and administrative organization corresponding to their simple needs. A further interesting advance towards this goal has just been made by the supervisory body. It has drawn up a pamphlet of some twenty pages entitled 'Notes on the Preparation of Estimates'. These notes fall into two parts: (1) notes for non-manufacturing countries which merely import their requirements, and (2) notes for manufacturing countries. The notes are in the nature of a guide which brings together for the convenience of the national administrations in a practical form the experience gained during the four years of the working of the Convention.

The increasing universality of the application of the Convention is shown in part by the record number of 63 ratifications which it has received—a figure higher than that obtained by any other Convention under the auspices of the League. It is also shown by the constantly increasing number of countries which, each year, furnish estimates, and the corresponding decrease in the number of estimates which the supervisory body is itself called upon to establish. In October 1933 only 45 countries furnished estimates. This figure rose steadily to 54 in 1934, 59 in 1935, 61 in 1936, and 63 in 1937. In the same way, the number of estimates furnished for territories rose from 83 in 1933 to 104 in 1937. The corresponding decrease in the number of estimates framed by the supervisory body itself is from 54 (23 countries and 31 territories) in 1933 to 12 (10 countries and 2 territories) in 1937.

A further sign of progress is the constantly increasing exactitude of the estimates furnished by Governments. The gap between the estimates furnished in advance and the statistics subsequently received of the actual trade operations covered by these estimates narrows from year to year.

It is nevertheless impossible to foresee all needs for each drug with complete accuracy in advance, and it is one of the tasks of the supervisory body under the Convention to examine supplementary estimates which Governments find it necessary to furnish during the

course of the year. Since the publication in November last year of the statement of estimates for the year 1937, the supervisory body has received and examined 118 supplementary estimates relating to the current year.

As regards the figures of drug requirements for the year 1938 contained in the statement, the following may be noted. The introductory table in the statement gives a total of estimated world requirements of each drug for medical and scientific purposes for the year. The total amount of morphine required for all purposes (including the amount required for conversion into heroin, codeine and dionine) is 45,638 kilos (as compared with 40,976 kilos in 1937). The amounts of heroin, codeine and dionine (made principally by conversion from morphine) estimated as required for 1938 are: heroin, 1,133 kilos (as compared with 965 kilos in 1937); codeine, 20,921 kilos (as compared with 25,724 kilos in 1937); dionine, 3,089 kilos (as compared with 3,199 kilos in 1937). The amount of cocaine estimated as required is 5,032 kilos (as compared with 4,976 in 1937). A little over a ton of other drugs is required. Altogether, therefore, leaving aside the factor of conversion, the total amount of dangerous drugs estimated as required for actual use next year is a little over 52 tons.

One of the principal tasks of the supervisory body under the Convention is to see that estimates are not excessive and correspond as closely as possible to real needs. In carrying out this task, the supervisory body asked for additional information and explanations in the case of eleven countries. Even here, four years' experience has shown considerable progress, since information of this kind was asked for in 1934 from 28 countries, in 1935 from 23 countries, and in 1936 from 18 countries.

Some 53 countries have so far signed the Procès-Verbal drawn up for the purpose of enabling the statement of the supervisory body to be issued on 1st December instead of 1st November; ten signatures are still required before the Procès-Verbal can come into force.

LEAGUE OF NATIONS,
INFORMATION SECTION.

16th December, 1937.

BOMBAY MEDICAL COUNCIL

THE following extracts from a summary of the proceedings of the meeting of the Bombay Medical Council held on 8th November, 1937, are published for information:—

The council proceeded to consider the position with regard to the (1) resolution passed by them at their February 1937 meeting that the Medical Council of India be urged that the Government of Portuguese India be requested to allow all medical practitioners registered under the Bombay Medical Act, 1912, to practise in Portuguese India and (2) the reply from the Medical Council of India that the matter is outside their scope and that any extension of local reciprocity should be negotiated for, by and at the discretion of the Bombay Medical Council and it was decided that the matter be referred back to the executive committee to consider and report on the question of advisability of further urging the Government of Portuguese India to allow all medical practitioners registered under the Bombay Medical Act, 1912, to practise in Portuguese India.

The council proceeded to consider the application of Dr. Hermann Selzer, M.D. (U. Rome), for registration under section 7(1) or 7(1a) of the Bombay Medical Act, 1912, and resolved that the matter be referred back to the executive committee (i) for stating the conditions under which tables (G) and (H) in the Bombay Medical Register showing the qualifications registrable as additional qualifications were drawn up and (ii) for finding out the names of the institutes in the Kingdom of Italy referred to in government notification, General Department, No. 6675, dated 12th October, 1937.

The council proceeded to consider the charge of giving a false certificate of death and consequently being guilty of infamous conduct in a professional respect against Mr. Dattatraya Sadashiv Pathre, M.B., B.S., and decided that he has been guilty of the charge and directed the registrar to erase his name from the Bombay Medical Register.

The council proceeded to consider further the application of Mr. G. S. Kasyapi, L.M. & S., for the restoration of his name to the Bombay Medical Register and resolved that the consideration of the application be postponed to the next meeting of the council and that he be asked to be present at that meeting.

The council proceeded to consider the proposal of the Government of Sind, forwarded by the Government of Bombay for opinion, that one out of the six seats of nominated members under clause (b) and two out of the six elective seats under clauses (c) and (d) of sub-section (2) of section 2 of the Bombay Medical Act, 1912, be reserved for Sind, and it was resolved by a majority that the present arrangement may continue until a separate council is formed for Sind.

The council proceeded to consider the proposal made by the executive committee that the Legal Department of the Government of India be requested to include in the new Insurance Bill a provision that insurance companies should employ only registered medical practitioners as medical examiners and referees and it was resolved that the Bombay Government be requested to represent the matter to the Government of India, that the president be authorized to write a memorandum making out a case for the employment of registered medical practitioners only as medical examiners and referees by insurance companies and that a copy of each of the resolution and the memorandum be sent to each Provincial Medical Council for such action as it deems proper and with a request that immediate effect be given to it.

The council proceeded to consider the position with regard to the resolution adopted by the Medical Council of India with reference to the correspondence regarding the question of recognition for registration of medical qualifications of the American universities, viz., 'that this council is of opinion that Indian nationals who have obtained qualifications of repute in foreign countries should not be granted recognition in India unless such foreign countries recognize the qualifications of this country on a basis of complete reciprocity', and it was resolved that the Bombay Medical Council agrees with the above resolution, subject to the proviso that the restriction embodied in that resolution should not be operative till the end of 1942 so far as the Indian nationals are concerned.

The council proceeded to consider the letters from the chairman of the Provincial Branch of British Empire Leprosy Relief Association (Indian Council) and the Government of Bombay, requesting, in accordance with the revised constitution of the branch, that a member be elected to represent the council on the provincial branch and Mrs. Cecilia D'Monte, L.M. & S., F.C.P.S., was accordingly elected as the representative of the council on the branch.

The council proceeded to consider and passed a motion made by Dr. Jivraj N. Mehta, M.D. (Lond.), etc., and seconded by Mr. C. A. Amesur, M.S. (Lond.), that the executive committee be requested to submit amendments to clause (7) of rule 12 of the rules of council regulating elections to the council so as to ensure secrecy of the ballot.

The council proceeded to consider and passed a motion made by Mr. U. B. Narayanrao, L.C.P.S., and seconded by Mr. V. D. Sathaye, L.C.P.S., that the proposal of the former, for amending (i) section 2 of the Bombay Medical Act, 1912, so as to fix the number of members of the council at 14, to provide for the election of the president annually, to reduce the number of nominated members from 6 to 4 and to increase the number of members elected under clause (d) from 2 to 5 and (ii) section 5 so as to omit the word 'previous' from clauses (1) and (2) of it, be referred to the executive committee in the first instance.

The council proceeded to consider and passed a motion made by Mr. V. D. Sathaye, L.C.P.S., and seconded by Mr. U. B. Narayanrao, L.C.P.S., that the council is of opinion that the practice of getting countersignature on medical certificates granted by registered medical practitioners is against the principles and spirit of the Bombay Medical Act, VI of 1912 [section 10(2)], and recommends to Government to put a stop to this practice and it was further resolved that the president be requested to take the matter up with the Honourable Minister and press for the acceptance of the council's view.

The council proceeded to consider a 'bill to prohibit the conferment of unauthorized medical degrees, etc., and assumption thereof' received from Government for the opinion of the council and it was resolved (1) that the council is in favour of the bill which is practically on the lines of the bill to amend the Indian Medical Degrees Act, 1916, previously submitted to Government by the council, and will communicate its views later regarding the details of the bill and (2) that the matter be referred to the executive committee for consideration and report.

The council proceeded to consider a motion made by Dr. Jivraj N. Mehta, M.D. (Lond.), etc., and seconded by Mr. C. A. Amesur, M.S. (Lond.), that the words 'under the Medical Acts or' in line 3 of clause (1) and in line 3 of clause (2) of section 10 and in line 8 of section 11 of the Bombay Medical Act, 1912, be deleted and that the words 'if reciprocity of registration has been arranged with the General Medical Council, London', be added between the words 'shall' and 'be' in line 2 of clause (1) of section 7, and it was resolved that the matter be referred to the executive committee in the first instance.

The council proceeded to consider a motion made by Dr. Jivraj N. Mehta, M.D. (Lond.), etc., and seconded by Dr. P. T. Patel, M.D. (Lond.), etc., suggesting (1) that the Bombay Telephone Company be requested to make certain alterations in their telephone directory, e.g., giving separate lists of 'Veterinary Surgeons' and 'Dental Surgeons', (2) including in the special list of 'Doctors' only those who hold medical degrees or diplomas, irrespective of the fact whether they are registered or not, and (3) showing the medical qualifications properly, etc., and it was resolved that the matter be referred to the executive committee for consideration and report and that the committee be requested at the same time to go into the question whether any action could be taken under the Indian Medical Degrees Act, 1916, against any of the practitioners mentioned in the directory.

INDIAN MEDICAL COUNCIL

COLONEL N. M. WILSON, Surgeon-General with the Government of Madras, has been nominated as a member of the Medical Council of India from the Presidency of Madras.

THE UNITED PROVINCES PHARMACEUTICAL ASSOCIATION

THE Annual General Meeting of the U. P. Pharmaceutical Association was held in the department of pharmaceuticals, Benares Hindu University, on the 19th November, 1937. After the acceptance of the annual report and audited statement of the accounts the office bearers of the council of the association for the year 1938 were elected.

The U. P. Pharmaceutical Association has been recently registered under the Societies Registration Act of 1860 and has the following aims and objects:—

(a) To train men for the profession of pharmacy in the United Provinces who will be at par with those in other civilized countries and to devise ways and means for the attainment of this ideal.

(b) To promote the cause of the science and art of pharmacy in all their different branches.

(c) To raise the status, outlook and ethics of those who are directly or indirectly engaged in pharmaceutical

(g) Persons who have been engaged in teaching pharmaceutical subjects, including chemistry.

A Medical Exhibition is also arranged. Those manufacturers who desire to reserve a stall, should inform the Honorary Secretary as soon as possible.

A burn lesion is not the burn alone but the burn *plus* all those consequences which develop because the treatment does not check them. The outcome of the treatment has in the past too often been considered as an unavoidable part of the original condition. Accordingly the treatment of serious burns has been approached with dread by physicians because of the limited benefits accruing from their management.

When tannic acid is applied to a burn and is followed by silver nitrate, a coagulum speedily forms which becomes impermeable to the further loss of body fluids and which immediately prevents additional fluid shifts. Through its speed alone in producing this change, it saves lives. This treatment by preventing dehydration minimizes shock and thereby carries the patient safely through the most critical period; that is, the first twenty-four hours following a serious burn. It therefore lessens one of the most fatal untoward effects of a burn.

A burn, however produced, results in injury to, or destruction of, the skin to a greater or lesser depth, frequently extending into the subjacent tissues. This injury to the outer protecting layer of the body quickly results in the formation of large or small vesicles, which may remain intact or which may become ruptured and ooze for a long time. Following a burn there begins at once the outpouring from the surface of the body of a great quantity of fluid. The loss of the outer layers of skin, those which act as a seal, allows this to take place unhindered. The serum loss rapidly reduces the amount of all body fluids. The removal of the protective layers of the skin alone by any means, including burns, results in a copious outflowing of serum. Such weeping outlets must be sealed at once to prevent dehydration.

In addition to the surface escape of fluid there is produced very early a reaction which calls for the pouring out of circulating body fluids into the tissues adjacent to the thermal injury. This local stagnation of fluids is also very large. Escape of fluid by means of the action of the sweat glands must also be added. These combined losses of circulating body fluids, namely, that which oozes from the body and that which stays in the tissues, are therefore not only voluminous but consequential, since Blalock, Parsons and Phemister, Harkins, Underhill, Kapsinow and Fisk and many other investigators have shown that traumatic shock is the result of the diminution and shift in circulating body fluids.

A brief review of some of the major points brought out by these experimenters is of interest. Animals were fixed on their backs in a trough suspended from above, in such a manner that the apparatus just balanced and was attached to a revolving, recording drum. Severe injury without bleeding was then produced to one side of the animal by burning or beating. Very shortly that side of the apparatus became heavier than the other. This shift of body fluids began promptly. Forty per cent of the maximum shift occurred within the first hour after the injury and continued in a gradually decelerating curve. In the course of these experiments the amount of circulating fluids lost was estimated in various ways: (1) by balancing the overweight of the burned side with weights on the opposite side and (2) by weighing separately the two sides of the animal after death. These authors further showed that the amount of blood obtained by bleeding an animal under an anæsthetic is an index of the circulating blood volume. In control dogs the bleeding volume averaged over 55 per cent of the calculated circulating blood volume. In shock due to severe trauma of the extremities, whether caused by a burn or otherwise, it was reduced to as much as 16 per cent. The shift from the circulating blood stream to and about the injured tissues consisted therefore of a very large percentage of the circulating blood volume. The figures representing the circulating fluid loss were further substantiated by excising sections of muscle from the injured and the uninjured side, weighing them and then evaporating them to dryness, and also by expressing the fluids under pressure. The same figures were obtained. These determinations were still further checked by frequent hæmoglobin estimations and hæmocrit readings and were compared with control animals similarly anæsthetized but otherwise uninjured.

The average loss of circulating body fluids following a severe burn was found to be 2.1 per cent of the total body-weight. As dogs do not blister and weep, this

loss was solely into and about the injured tissues. It was out of the circulation though not out of the body. The deprivation of a large volume of circulating body fluids is therefore shown to be the direct cause of shock, which will become manifest when the fluid reaches a certain low point. However, other factors may increase it. Other experimental evidence also shows that the blood pressure holds up fairly well until shortly before death. It falls only after the heart output is reduced, when shock supervenes. The blood pressure is therefore not a reliable criterion of the condition of the burned patient. Hæmoglobin determinations, on the other hand, give much more reliable information and should be made frequently. The fluid that escaped into subcutaneous tissues after an experimental burn showed some chloride increase over the fluid portion of the blood. Sugar and non-protein nitrogen were not changed, and the protein content was somewhat lower. It very closely resembled blood plasma.

It follows, then, that when a part is burned or otherwise injured there is produced in and about that area an altered physiology. A call goes forth that results in a rapid and great seeping of fluids into, and adjacent to, the injured area. A considerable fluid loss thereby is rapidly attained. However, when such a traumatized region is treated at once by the application of tannic acid followed by silver nitrate, all the destroyed and injured tissues down to the very borderline of impaired cells are picked up and fixed in an innocuous, non-absorbable coagulum.

The shift of the circulating body fluids into the tissues adjacent is halted at once. The necessity for prompt and complete stoppage of all fluid losses is imperative. A treatment that requires more than an hour in which to seal up the leaking surfaces and to control the fluid shift is therefore to a high degree inefficient. Tannic acid and silver nitrate applications which act instantly are therefore most efficient. The practical importance of speed in the initial treatment of burns is manifest when it is recalled that 60 per cent of the deaths from burns occur in the first twenty-four hours, nearly all from traumatic shock.

What are the practical applications of the foregoing facts to a man of say 155 pounds (70 kg.)? The calculated blood volume, being one-thirteenth of the body-weight, is therefore 12 pounds (5.4 kg.). The total amount of circulating body fluids is about 60 per cent of the calculated blood volume, or 7.2 pounds (3,266 gm.). The loss of 2.1 per cent of the total body-weight therefore would be 3¼ pounds (1,474 gm.). This is lost between 40 and 50 per cent or even a greater amount of the entire fluid portion of the blood. It was also determined by comparison with experimental animals that a burn of one-sixth of the body surface of a 150 pounds (68 kg.) man may cause a loss of 3,500 c.c. or 70 per cent, a staggering amount, of the circulating body fluids in the first twenty-four hours.

The efforts of nature to overcome an injury by dilution of the obnoxious agent call for the outpouring of fluid into the surrounding and adjacent tissues. This produces œdema of the intercellular spaces and widespread swelling. When tannic acid and silver nitrate are applied, the seal they provide exerts an influence that is beneficial beyond anticipation. The changes in the surface come with great promptitude. What was but a moment ago a red, wet, oozing, irritated surface is now covered with a black, smooth, dry, leathery eschar, soft and flexible, yet firmly attached and acting as a protection from injury from without, as well as being an occlusant against the loss of fluids from within. The usual widespread and important systemic effects of the burn are not noted. Untoward reactions are absent and the picture is entirely different from that seen when other treatments are used.

With this treatment, the temperature usually does not rise above 101°F. even in extensive burns, and the pulse and respiratory rates are proportionately low. The red blood cell counts remain remarkably near normal, as do also the white cell counts. Only a few staff cells are present.

Gunn and Hillsman state that kidney damage occurs so regularly and so early that it may be taken as a part of the phenomena of burns and not be classed as a complication. Yet, when the tannic acid-silver nitrate treatment has been used, urinary suppression has never been seen, nor has albumin been present, or other abnormal elements, in the absence of grease or oil applications, except sugar, which may be present in the early specimens following any burn. The minimal systemic effects are a notably outstanding feature of this regimen.

When wet solutions are applied to tissues, normal or injured, over a long period, there is produced a reaction which is threefold; oedema, maceration and infection. The presence of fluid, tannic acid solution, saline solution or what not, in contact with tissues over many hours is responded to by a dilatation of the neighbouring blood vessels and an outpouring of fluid into the tissues. In addition, there is absorption of portions of the fluid into and about the injured area. A combination of these actions, therefore, results in the escape of increased amounts of fluids into the intercellular spaces. These spaces, becoming engorged, produce a very considerable enlargement of the extremity. This takes place when for example wet packs are applied as to a hand. However when tannic acid and silver nitrate are applied, the period of the application being but a few minutes at most, there is not time for the dilatation of vessels, for the outpouring of fluids from the circulation, for the absorption of fluids from the surface or for weeping.

Substances such as may be present as a result of the tissue destruction and which may produce local reactions causing intercellular oedema are grasped and held at once permanently in an insoluble, non-absorbable, irreversible matrix. There are therefore no irritating substances beneath the coagulum to call out a reactive response. There is no outpouring of fluid, no oozing, no overfilling of the intercellular spaces, no oedema, no enlargement of the extremities and no increase of pressure within the coagulum. There are no toxins or other deleterious substances to be absorbed.

In practically all burns there remain unimpaired many epithelial islands of skin and of the deep glands. The long application of any solution breaks down many or all of these. Tannic acid and silver nitrate save these centres of epithelization, and speedy healing with lessened scar tissue is therefore promoted.

By the use of tannic acid and silver nitrate, there being no fluid on the surface for long periods and the casing formed being dry, non-absorbable and of a composition which is not a good culture medium, infection is prevented. The wound is dry and clean from the onset and is kept so throughout.

Contrariwise, when grease or oil in any form has been applied, whether as the burning agent or as the treatment, even though complete removal is attempted, there will remain areas which are not as dry as when grease has not been applied. Grease and oil applications should never be made to any burn.

When slow acting coagulating applications are made there is much oedema, which progressively increases the tension of the tissues within the slowly forming casing. The application of tannic acid followed by silver nitrate produces an eschar under which there is little or no increased tension. An objection to the use of tannic acid alone is the loss of digits, which sometimes occurs. The marked difference in the tannic acid alone and the tannic acid-silver nitrate treatment in this regard is distinctly shown in the cases to be cited:

Case 1.—Baby C., aged 5 months, received a burn of the entire right upper extremity, the chest and the face. The tannic acid-silver nitrate treatment had not yet been used on extensive burns and was used only on the chest. Tannic acid alone was used on the extremity and the face, according to established technique. The leatherization took place over a period of some hours, with another period for drying. During the time that the coagulum was forming an outpouring of serum from the surface as well as into the subcutaneous and deep tissues was taking place, as was also some absorption of fluid from the surface. These actions continued concurrently with the formation of the leatherized

encasement, and the extremity became confined within a slowly forming but nevertheless firm case. The oedema progressively increased and the pressure within the casing increased with it and finally became sufficiently great so that the venous return flow was impeded, as was also the arterial circulation. The hand sloughed off at the wrist just below the point at which the circulation was superficial and therefore most easily compressed.

Case 2.—R. B., a man, aged 45, received a 54 per cent (by actual measurement) gasoline burn extending from the top of his head to his right ankle. He was seen shortly after patient 1. So seriously burned was he that three physicians told him that his condition was hopeless. The burn of the hand and arm was more severe than that of the child, and his general condition was also very much worse. When I saw him four hours after the accident a considerable loss of circulating body fluids had already taken place. The haemoglobin was 165 per cent of normal and the red blood count showed concentration in proportion. Tannic acid was applied from head to foot, followed by silver nitrate. The oozing was stopped almost instantaneously and within a few minutes the surface was dry and there was no further increase of the dehydration. Albumin was never present in the urine. The outpouring of serum into the adjacent tissues was also stopped with promptitude. Encasement of more than half of the body surface, including the entire right arm and forearm, both wrists and hands and right leg and thigh, head, back and other parts, was quickly accomplished. A firm, dry, thin, leather-like covering was formed. The blood vessels of the wrists and elsewhere were not impinged on and the circulation of the burned extremities was not interfered with. There was little or no increase of pressure within the casings. The passage of but a few days showed that both hands with all fingers would be saved intact. He was all healed and well by the forty-second day and to-day has no impairment of function of the fingers and hands and no scarring anywhere except on the back of the right hand and forearm, where Thiersch grafts were applied on the twenty-sixth day.

The contrast of these two cases is very vivid. Not only was this life saved by the prompt action of the medicaments but his hands also by the absence of undue pressure within the rigid encasement which covered the extremities like a glove. It is not intended to convey the idea that digits may never be lost under this treatment, but they are not lost because of oedema within the coagulum.

Three cultures taken from beneath unbroken tanned and dry coagulum on two seriously burned patients showed no growth of organisms, but cultures taken from uncovered areas showed *Staphylococcus albus*. The dry surface of treated areas is not a good culture medium for bacteria, and this condition is augmented by the antiseptic action of the silver present in the coagulum. From early periods silver, both in the metal and in the salts, has had wide usage for the prevention of infection in wounds, and surely it is here applied to a maximum effect.

That no absorption of silver takes place even when extremely large amounts of solution are used is proved by the fact that in none of the many cases treated has argyria or other evidences of silver absorption been seen, although carefully watched for. It has not been noted by other surgeons who have reported experience with this treatment.

Patients treated with tannic acid followed by silver nitrate are remarkably comfortable at once. Many patients are ambulatory from the beginning or at a very early date, frequently even when portions of the lower extremities or the torso are the sites of injury. Even in very extensive burns, patients move about quite freely in bed. The extreme systemic effects of the burn are greatly attenuated. Irrational periods are present only in very large burns and are of short duration.

A serious burn affects all the vital organs unless stopped by efficient treatment. When dehydration occurs, it lowers the heart output and makes difficult the carrying on of the vital processes by the blood cells

operating in deficient fluids with increased viscosity and resulting anoxemia. The lessened aeration of the blood is the effect of the difficulty in taking on oxygen and giving off carbon dioxide and other waste products. Toxic substances are excreted with difficulty and incompletely. The blood chemistry particularly is changed. The absorption of degenerated tissue and bacterial toxins modifies the action of all the organs and tissues within the body. It is proposed to discuss the blood chemistry phase of this treatment at another time. These untoward effects are not seen when the burn is early treated with tannic acid and silver nitrate as directed.

The treatment of burns with tannic acid alone has proved far superior to greases and oils and other applications. While the use of tannic acid alone, as brought out by Davidson, is a decided advance over applications of grease and oil, yet it is not comparable to the tannic acid-silver nitrate method. The tannic acid alone and the dye treatments act in hours. Tannic acid followed by silver nitrate controls the condition in minutes. As stated earlier, red blood cells and albumin do not occur in the urine of patients under the tannic acid-silver nitrate regimen in the absence of applications of grease or oil; but when these applications have been made there is always albumin in the urine, even though an attempt has been made to remove them.

In the latter case the deficiency in the stoppage of the fluid loss through weeping and oedema is but slightly less than when grease has not been applied, not sufficient to make an appreciable difference in the concentration of the blood, yet this slight surface moisture is enough to permit the entrance into the blood stream of toxins or other elements that are present on the surface and to allow some infection to develop. The absorption of some substance or substances from the surface must account for the presence of the albumin in the urine.

Concentration of the blood by itself is not sufficient to explain the albuminuria, for it does not appear in other conditions in which dehydration is a marked factor, such as cholera, persistent diarrhoea, severe hæmorrhage and prolonged vomiting. Something other than fluid loss must be responsible for the injury to the kidneys, spleen, liver, adrenals, blood production mechanism and other internal organs. Also, when grease or oil has once been applied the temperature, pulse, respiration, blood counts and the like are increased over what they would have been had such application not been made. The breaking down of protein and the slight infection that develops must account for the presence of substances which are promptly absorbed and which give systemic reactions.

One pictures mentally the terrible painfulness of daily or more frequent dressings of a seriously burned child treated by carron oil or other oil and applications of grease. The infection is always so great beneath the dressings that frequent removals are imperative.

With tannic acid alone the maximum problem of nursing is the often to be repeated applications by swabbing, spraying or packs, with their almost continuous disturbing of the patient. As the coagulum slowly forms the loss of circulating body fluids continues, and this loss must be made up by repeated intravenous, subcutaneous or rectal administrations of fluid, for the stomach retention is usually at a low point at this time.

With tannic acid followed by silver nitrate, one thorough application of the medication and the patient is allowed to rest in his bed warmed by electric lights, being disturbed only once or twice or may be three times for the giving of intravenous fluids. Surprisingly early is the mouth intake and the stomach retention sufficient to meet all requirements. Frequent hæmoglobin estimations are the simple, easy and ever at hand guide that should determine the amount of the fluid intake. Following a serious burn a minimum of 1,000 c.c. of fluids should be given every twenty-four hours for every 25 pounds (11 kg.) of body weight, and this should be more or less equally divided throughout this period.

In the early part of the first twenty-four hours a very liberal proportion of the fluids should be given, but care is necessary, especially in children, to see that too large a quantity is not given at any one time. The sudden throwing of 500 c.c. of fluid into the blood stream of a patient weighing say 50 pounds (23 kg.), and who normally has but 4 pounds (1,814 gm.) of blood, would dilute the circulating body fluids 25 per cent or more.

When the hæmoglobin reading is nearing normal, care should be used in giving extra-alimentary fluids. A diplomatic nurse will have no difficulty in persuading her patient to take the required amount of water, fruit juices and the like by mouth after the earliest hours, provided it is properly distributed throughout the waking period. The necessity for including salt must not be overlooked, and dextrose also.

Instead of the nurse bending her efforts toward the production of a good coagulum, she has no concern with this feature, as it has already been accomplished by the twofold application, and she therefore spends her time in keeping the patient warm and the coagulum dry and in forcing fluids.

By this procedure the coagulum is formed by the combination of tannic acid with the body fluids and then by a union of the silver nitrate with this first combination. The application of tannic acid produces a greyish-white precipitate, which instantly becomes black when in contact with the silver nitrate. Metallic silver is precipitated into the mass, where it is fixed. Any heavy metal would undoubtedly act in much the same way if used when silver nitrate is not available, but the good offices of the silver would be lacking.

Burns treated with oil and grease heal slowly, become infected, form abundant scar tissue and have a long and trying period of hospitalization. The treatment by tannic acid followed by silver nitrate, in the absence of oil and grease, promotes smooth healing. There is little or no infection beneath the coagulum, there is minimum scarring and a short period of hospitalization, frequently none at all, and there are no dressings to be changed. Many patients are entirely healed beneath the coagulum when it comes away.

Our records show that the hospital confinement period has been reduced to one-fourth the time by this treatment. In other words, it takes only weeks now for recovery whereas under former treatments months were required.

The tannic acid-silver nitrate treatment of a burn is carried out as follows: The patient is given a narcotic, which is repeated as often as may be necessary for comfort. Fluids must be forced throughout. Grease and oil in any form should not be used. If such an application, unfortunately, has been made, it must be removed with ether, benzene or ethyl acetate before treatment is applied. All blebs are to be opened and all loose skin and other burned tissues are to be removed. A thorough application of fresh 5 per cent tannic acid solution is made by means of cotton swabs. Following this, 10 per cent silver nitrate solution is applied in the same manner.

The local treatment now being completed, the patient is placed in a tent heated by electric light bulbs and the burned areas are dried and kept dry. In a few days the coagulum begins to loosen and is removed as early as possible. When it comes away, large areas and not infrequently all the burned surfaces will be found to be entirely healed. Occasionally moisture will be hidden beneath crusts where drying has not been satisfactorily accomplished, and such areas are unhealed. When the coagulum is adherent but loose, it is removed, a scalpel being used if necessary. Unhealed areas are treated by the application of oxyquinoline sulphate scarlet R gauze, in a single layer over which a light pad of dry gauze is placed, and healing is greatly speeded up.

The schedule here outlined—the avoidance of grease and oil, the giving of a narcotic, the application of tannic acid followed by silver nitrate, drying the coagulum, keeping it dry and removing it early, forcing fluids and the stimulation of epithelization—constitutes a superior method of treating serious burns. Less skin

grafting and other reconstructive measures are required. There are minimum scars, and greatest of all is the saving of lives that would otherwise be lost.

Air Warfare and the General Practitioner

By L. H. GUEST, M.R.C.S., L.R.C.P.

(From the *Practitioner*, Vol. CXXXIX, August 1937, p. 139)

If air war should come to this country, the general practitioner and every practising or active member of every section of the medical profession will need to have certain special and technical information to help him in his treatment of cases and in his recommendations for the prevention of casualties.

The practitioner must have:—

(1) A knowledge of the outline of the methods of air warfare and of the characteristics of modern military aircraft and bombs.

(2) A knowledge of the effects of incendiary substances and poison gases as well as of high explosives on the human body.

(3) A knowledge of the emergency means of protection for individuals given by the different types of respirators, viz, the 'General Civilian', as used by the general population, the 'Civilian Duty', as used by certain medical and ambulance services and by key-men and women at special points of importance in public services and the 'Service Respirator', as used by soldiers, the police, special services, A. R. P. doctors and others.

(4) A knowledge of the methods of preventive anti-gas treatment for the avoidance of damage by blister gas.

(5) A knowledge of the methods of decontamination of the clothing of individuals: (a) as a preventive measure and (b) as a method of cleansing from blister gas.

(6) A knowledge of the methods of decontamination of roadways, houses inside and out, contents of houses, motor cars, public service vehicles and in general all material objects.

(7) A knowledge of the means of constructing gas-proof refuges in private houses, offices, workshops or factories or public buildings.

GENERAL CONSIDERATIONS

The practitioner will need this information partly for his own use and application in his practice for purposes of treatment should need arise, and partly in order to be able to hand the knowledge on to his patients who will certainly apply to him for information.

It must be emphasized that the question of the propriety and necessity of acquiring this knowledge of air warfare and especially of gas warfare is quite distinct from the question of the nation's policy of peace or war. No one reading the daily newspaper to-day could fail to realize that war is not only a great danger but a definite and terrible practical possibility. How to avoid that war, how to guide the nation's policy into the ways of peace should be a matter of day and night consideration not only for statesmen but of all responsible men and women. But apart from this duty which is incumbent on the individual medical practitioner and on the medical profession as a whole as on every profession, the general practitioner has the special duty of knowing how to treat air raid casualties if they arise and how to use special knowledge to prevent casualties under air raid conditions in so far as it is possible to do so.

In the absence of such knowledge an air raid would lead to panic and to serious panic casualties quite apart from anything an enemy might do. And in this panic an attacked population would be in the situation most exposed to attack and least defended against it. It may be said that the education of the general public cannot be entirely saddled on to the backs of the medical profession, and that is true. The Government will issue information to the general public from time to time and the number of lectures given by the Order of St. John, the British Red Cross Society, and the Order of St. Andrew will increase and carry knowledge

to an ever-widening audience. A further source of knowledge will be in the nursing profession all of whose members are eventually to receive instruction of the same kind as that given by Home Office medical instructors to medical practitioners. In one way or another, therefore, the amount of knowledge of air attack and of air raid precautions will go on increasing steadily. And the question of treatment of casualties and of methods of avoidance of danger and of prevention of casualties which are very largely medical questions will more and more come to the fore in public discussions, and more and more practitioners will be asked questions about them.

Many questions will be asked to which the medical practitioner will not be able to give a complete reply but it is possible to indicate if not the outline of a complete reply at least the outline of a direction of inquiry. Many people are concerned about the danger of high explosive bombing from the air. The reports from Spain and the story of Guernica in particular have impressed themselves vividly on the popular mind. But an air attack on Guernica, an open undefended town with no defending air force, with no anti-aircraft guns and without air raid precautions of any kind apparently, bears no comparison with a possible air attack on any part of the British Isles. In Great Britain there is an efficient Air Force, efficient anti-aircraft guns and other means of defence and an efficient air raid precautions organization is being built up. Nor is there any direct comparison possible between an attack on a small township as a demonstration of 'frightfulness' and an attack on this country which would have to be aimed at vitally important military objectives. The mere area of London and the industrial area of Birmingham, Lancashire, Yorkshire and other parts of the country make attack difficult. No foreign power has enough aeroplanes to attack more than one comparatively small part of these great areas at a time.

HIGH EXPLOSIVE AND INCENDIARY BOMBS

In reply to a question about high explosives it may, therefore, be said truthfully that the larger part of the country will never be attacked at all and that in areas attacked it will be primarily points of military importance (e.g., docks) which will suffer and houses and flats only incidentally because of their proximity to these points. Incendiary attack by small 2-lb. thermite bombs will be more widespread and may possibly include residential areas but the increased and strengthened fire-fighting services being set up with the aid of the Home Office will attend to that.

MUSTARD GAS

All the gases dealt with so far have been those affecting eyes, nose or lungs. Any one of the three types of respirators, i.e., 'General Civilian', 'Civilian Duty' and 'Service', will give complete protection against them because the rubber face-piece covers the whole face including eyes and nose and the air-filter cleans out the gases from the air before it is breathed in. The tear gases and the lung irritants are absorbed by the granulated charcoal which the respirator filters contain: the nose irritants are filtered out by layers of special wool. The nose-irritant gases, it should be mentioned, are in reality particulate clouds which the layers of special wool filter out. But the next group of gases, the blister gases, not only affect eyes, nose and lungs but also any part of the skin, or of the digestive tract which vapour or liquid can reach.

The respirators, all of them, give complete protection to eyes, nose and mouth and lungs, but the respirator on the face does not, of course, protect the skin of any other part of the body. The effect is one produced by direct contact. It has nothing to do with any absorption from any other part of the body.

The important member of this group is mustard gas, and it was used very extensively in the Great War. It is less deadly than the lung irritants but it has greater casualty-producing power because of its action on the skin. The current phrase describes this effect of mustard gas on the skin as a 'burn' and indeed it is treated as a burn and heals as a burn. But it is not a burn in any ordinary sense. If mustard gas,

which is liquid normally, is applied to the skin it causes no more sensation than any other liquid of similar properties, say a light motor-engine oil. Only after some hours does erythema, followed by blistering, show itself. The vapour has the same delayed action whether applied to the skin (in the case of clothing being contaminated with drops of the liquid and giving vapour off between clothes and skin) or whether breathed into the lungs, where it produces the same kind of inflammatory destruction. If there is much vapour of mustard gas in the air, the eyes become inflamed as the skin does, but the proportion of serious injuries and partial or complete blindness is uncommon. There is always delay in the onset of symptoms after exposure to mustard liquid or vapour and it is this insidious character which makes it such a potent casualty-producing agent.

Mustard gas is generally a difficult thing to deal with. It is a stable chemical substance, dichlorodithiyl sulphide by name, an oily, dark-coloured liquid in its ordinary commercial form, giving off a vapour at ordinary temperatures, but only evaporating slowly so that if discharged on the ground it persists for a long time and on metal or impermeable stone for weeks. Mustard is also a penetrating substance. It is readily absorbed by everything except metal, glass, porcelain, or a specially prepared surface of oilskin or certain chemical paints. On the skin it is absorbed as readily as ink by blotting paper because although almost insoluble in water it is readily soluble in the fats of the body. It is also readily dissolved by paraffin, petrol and alcohol. Any food on to which mustard liquid falls or which is exposed to mustard vapour rapidly absorbs it and if eaten subsequently gives rise to the characteristic mustard inflammation of any and every part of the digestive tract which it reaches. There is no immunity to mustard gas, one exposure indeed markedly increases sensitivity and for a period of years, and the poison is also cumulative. Exposure to comparatively small doses of vapour, for example, over a period of a week as under conditions in trench warfare will give rise to skin, throat and eye trouble.

This means shortly that every person exposed to mustard liquid on the skin or clothing or to mustard vapour in sufficient concentration in the air will, if unprotected, become a casualty. And as the mustard liquid is persistent, it will, even if it has soaked into the ground, or into a wood floor or into brick work, continue to give off vapour until the whole of it is slowly evaporated. Mustard gas, therefore, presents the doctor with two major problems: the problem of treatment of affected persons and the problem of prevention of further casualties by removal or destruction of the mustard liquid discharged on to any material object. There is one quality of mustard, however, of which advantage can be taken in treatment. Mustard liquid on the skin is not absorbed at once, it takes about five minutes to penetrate the epidermis. And mustard liquid on the clothing takes about twenty minutes to penetrate it and to produce a poisonous vapour between clothing and body. If, therefore, an individual whose skin is sprinkled with mustard liquid or if his clothing has been sprinkled within five minutes of his clothing from top to toe within twenty minutes, then that person will be prevented from developing mustard lesions. But the time is short. There is no space here to go into the question of the diagnosis or detection of mustard, its indefinite smell of garlic or of its use in bombs or in the form of a spray from a special spraying tank of an aeroplane, but at a time of air attack it may be assumed with practical certainty that mustard will be used.

Measures must therefore be taken to deal with possible large numbers of mustard gas cases at first-aid posts where 'anti-gas' treatment for individuals, that is removal of mustard from the skin and decontamination treatment for clothing, can be given at once. Quite clearly, however, it will be a great advantage to everyone, in view of the time limit for preventive treatment being so short, if anti-gas treatment (that is,

removal of mustard from the skin) and decontamination treatment of clothing can be performed by the individual at home.

Mustard liquid should be removed from the skin by (i) dry swabs of cotton-wool applied vertically to the surface, all wiping being avoided and a separate piece of wool being used for each small area, (ii) dabbing off areas so cleared of obvious mustard liquid by cotton-wool dipped in surgical spirit (or paraffin or petrol in an emergency) so as to dissolve any mustard not removed by the dry swab and (iii) rubbing into the cleansed area a cream (bleach cream) made by mixing bleaching powder and water together in such proportions as produces a creamy application. The swabs used to absorb mustard must be placed in a tin with a tight-fitting lid until they can be burned. The bleach cream should be left in contact with the skin for one minute and then removed by washing off with water. If available, protective ointment, as recommended by the Air Raid Precautions Department, and which will be supplied to first-aid dressers, stretch-bearers and A. R. P. doctors, can be used instead of a dry rag. In any case of mustard gas on the skin, the eyes should be washed out with plain water as a routine. Any patient with mustard liquid on the skin will also have it on the clothes although there may be cases of persons with contaminated clothing in which the bare skin is not affected. All contaminated clothing must be removed, hat, outer clothes, underclothes and boots or shoes and the whole body washed over with water. If there is any suspicion of penetration of mustard in the skin, bleach cream must be rubbed in and washed off after one minute's application.

The governing consideration is that of time. Anti-gas treatment must be given within five minutes of the mustard reaching the skin. Decontamination treatment must be given within twenty minutes. Contaminated clothing when removed continues to be a source of danger. It should, if possible, be placed in a dustbin-like container with a close-fitting lid. If nothing is available, put it outside in a yard or garden and cover over with other clothes, old blankets or otherwise. Treatment based on these principles will be given at first-aid posts and decontamination centres, but the more people who understand how to do this for themselves the better for them and the better for all concerned, as congestion at first-aid posts will be avoided.

A Rapid Method for the Direct Estimation of Urea in Urine

By SYDNEY W. COLE, M.A.

(From the *Lancet*, Vol II, 4th September, 1937, p. 575)
The general use of the blood urea-clearance test for renal efficiency has drawn attention to the desirability of an accurate method for the estimation of urinary urea which can be carried out with simple apparatus and which does not involve the simultaneous estimation of urinary ammonia. From experience gained by noting the work of some hundreds of my pupils during the past four years, I have modified the direct method I published in 1931. It is now conducted much more rapidly and the technique is so simple, that the results obtained are the most accurate of all the quantitative methods of analysis carried out in class work.

TECHNIQUE

Solutions.—1. N/6 HCl, prepared by diluting 100 ml. of N.HCl with 500 ml. of distilled water.
2. Acid potassium phosphate, KH_2PO_4 , 3 per cent.
3. Brom-thymol-blue, 0.04 per cent.
4. 'Mixed Indicator'. Mix equal volumes of a 0.02 per cent solution of methyl-red in 60 per cent alcohol and of 0.04 per cent aqueous solution of bromocresol green. The indicators are conveniently stored in bottles carrying dropping pipettes. The 'mixed indicator' should be freshly prepared about every two months, the methyl-red being somewhat unstable in the mixture.

5. Dilute caustic soda (about 0.1 N) in a bottle fitted with a dropping pipette.

6. Mercuric-ammonium chloride. Dissolve 0.5 g. of mercuric chloride in 250 ml. of distilled water. Add 250 ml. of a cold saturated solution of pure ammonium chloride. The solution should be stored in a bottle fitted with a cork carrying a 1 ml. pipette that has a safety bulb above the mark. It should be labelled *Poison*.

7. Urease. Transfer 5 g. of powdered jack bean meal to a 150 ml. flask, with a narrow neck that can be sealed with the thumb. To 10 ml. of the acid potassium phosphate add 90 ml. of distilled water. Pour this on to the meal. Seal with the thumb and shake vigorously for a minute. Filter through a pleated filter paper. The first 10 ml. generally come through cloudy and should be refiltered. The urease solution should be kept in a refrigerator when not in use. When thus stored it is sufficiently active after a month, but it is advisable to prepare extracts every week.

Apparatus.—A 5 ml. micro-burette (A) and a 2 ml. micro-burette (B). These are filled to the mark with the N/6 HCl. The two burettes are conveniently clamped in a double Fisher burette-holder.

A 1 ml. pipette for the urine. It is advisable to use an Ostwald pipette, calibrated for delivery by blowing out after drainage.

A 5 ml. pipette for the urease.

A can of water at 40° to 45°C.

Boiling tubes, 6 by 1 inch.

Method.—Label two similar (in diameter) boiling tubes A and B. Into each measure 1 ml. of the urine, and to each add 3 drops of brom-thymol-blue.

To A add 5 ml. of the urease and warm gently in a flame. As soon as the fluid goes blue run in acid from the A burette to maintain a green tint (about pH 7, the optimum reaction for urease). Continue to add the acid as required, warming occasionally, but avoiding heating over 45°C. Generally in about 1 or 2 minutes the reaction appears to be completed. Place the tube in the water bath for another 5 minutes to ensure completion of the hydrolysis of urea to ammonium carbonate. Place the tube in a beaker of cold water whilst the control is being prepared.

To B add 1 ml. of the mercuric-ammonium chloride to inactivate the enzyme. Mix thoroughly and then add 5 ml. of the urease, being careful to prevent any transference of mercury to the bulk of the urease. Add 20 drops of the mixed indicator. Titrate, cautiously, from the B burette through green and steel grey to the first definite mauve tint.

To A add 1 ml. of the mercuric-ammonium chloride and 20 drops of the mixed indicator. Continue the addition of acid to this from the A burette through grey to the first definite mauve tint. This colour fades at first, due to the slow conversion of H_2CO_3 to H_2O and CO_2 . When the colour is permanent, add distilled

water to B to make the volumes of the fluids the same in the two tubes. This may cause B to go grey. If so add a trace more of acid from the B burette to make the colours match. Should the titrations of either tube be overshoot, add the dilute alkali drop by drop, to the more acid tube until the colour is just mauve. Add exactly the same number of drops of alkali to the other tube. Titrate the tubes, from their appropriate burettes, until the colours match at a mauve tint.

Calculation.—The difference between the amount of acid required for the two tubes is a measure of the urea decomposed to ammonium carbonate in A.

Since 60 g. of urea give 2 mols of $(\text{NH}_4)_2\text{CO}_3$ and this is neutralized to pH 5 by 2,000 ml. of N.HCl.

Then 1 ml. of N/6 HCl = 5 mg. of urea.

So difference in ml. of acid required $\times 500$
= mg. of urea in 100 ml. urine

and $\frac{\text{Difference in acid}}{2} = \text{g. of urea in 100 ml. urine.}$

NOTES

1. The urease solution can be made by extracting 5 g. of the jack bean meal (about a teaspoonful) with 100 ml. of distilled water and filtering. The filtrate contains more protein than in the preparation described above. The protein is precipitated at the final end-point of the titration, and somewhat obscures the end-point. The cloud in the A tube is always somewhat greater than in B tube, for some reason that I have been unable to determine. With the plain water extract there is always a marked increase in turbidity on allowing it to stand in the refrigerator. A good deal of this clears up on warming to room temperature.

2. The urease prepared by extracting with 0.3 per cent KH_2PO_4 is rather acid, generally about pH 5.8. It is convenient, though not necessary, to treat the filtrate (generally about 80 ml.) with 5 ml. of a 4 per cent solution of $\text{Na}_2\text{HPO}_4 \cdot 2\text{H}_2\text{O}$ (Sørensen's salt). This gives a clear solution and the initial rate of action is much accelerated.

3. The optimum pH for urease is about 7, but it increases slightly as the concentration of urea becomes very low. If desired a fluid of pH 7 can be prepared by mixing 6 ml. of the 4 per cent solution of $\text{Na}_2\text{HPO}_4 \cdot 2\text{H}_2\text{O}$ with 4 ml. of the 3 per cent solution of KH_2PO_4 and adding 20 ml. of distilled water. About 7 ml. of this can be placed in a boiling tube with 3 drops of brom-thymol-blue. The fluid in A should be kept at about the same tint as this, as near as possible. If the mixture is allowed to become a deep blue and is warmed to 45°C., there is a slight loss of volatile ammonia and the enzymatic reaction may not be completed. There is no loss of ammonia at pH 7 and with a normal jack bean meal the hydrolysis of the urea in 1 ml. of a urine that contains 2 g. per 100 ml. is complete in 3 minutes at 40°C.

The apparatus and materials required can be obtained from Messrs. Baird and Tatlock, London.

Reviews

POST-GRADUATE SURGERY.—Edited by R. Malngot, F.R.C.S. (Eng.). Volume III. (Hernia, Eye, Ear, Nose, Pharynx, Larynx, Oesophagus, Diaphragm, Endoscopic Methods, Jaws, Teeth, Tongue, Plastic Surgery, Obstetric Surgery, Cardiovascular and Lymphatic Systems, Venereal Diseases, Deep X-Ray Therapy, Physical Medicine, Orthopaedics, etc.). Medical Publications, Limited (37, Bedford Square, W.C.1), London. Pp. xi plus 3573 to 5584 with 1,015 figures in the text. Price, 70s. per volume or £9-9-0 per set of three volumes. [Complete in three volumes. Sold in complete sets only. Price, Rs. 140, Payable Rs. 10 per month: 10 per cent discount for cash. Only available from Messrs. Butterworth and Company (India), Limited, Calcutta]

With the publication of the third volume, this monumental work has now been brought to a successful

completion. We have no hesitation in declaring that this publication is entitled to be regarded as a standard reference book in surgical literature. The outstanding success of this work is in no small measure due to the harmonious collaboration of the numerous and eminent contributors. Although it is primarily intended for post-graduate students, no practising surgeon could afford to be without it.

The present volume, dealing mainly with special subjects, consists of 23 parts comprising 2000 pages of written matter and 1,015 figures in the text. It opens with an important contribution by Dr. Sleigh Johnson on the medical aspects of surgery. It is in evaluation of the 'surgical risk' and adoption of remedial measures that the physician can most usefully serve his surgical colleague. To the common but important lesion, hernia, Mr. Ogilvie devotes six chapters, admirably covering the subject. Plastic surgery, as a result of war

experiences, now occupies an important place in surgical practice. There are ten chapters on this subject by Mr. Pomfret Kilner, including mammoplasty and face lifting. The next part, consisting of six chapters, deals with obstetric surgery and is in the capable hands of Dr. Aleck Bourne. The difficult subject of cardiovascular surgery follows and it is amply covered in five chapters by Mr. Cokkinis. The next part is an exhaustive treatise on the lymphatic system. The first three chapters are by the editor himself, dealing with inflammation and tuberculous cervical lymphadenitis. On the dissemination of malignant disease, Mr. Sampson Handley writes convincingly with the authority of experience. Then follows an instructive article on elephantiasis by Dr. Manson-Bahr. Sir Humphrey Rolleston writes on Hodgkin's lymphogranuloma. The treatment is still very unsatisfactory but a sensitized vaccine of the 'elementary bodies' has given very encouraging results in early cases. There is also an informative chapter on glandular fever by Dr. Box. The remaining three chapters are by Dr. Sleight Johnson and are devoted to differential diagnosis, thymus and status thymo-lymphaticus.

Considerable space has been allotted in this volume to special subjects. With the incorporation of four chapters on orthopædics by Mr. Buxton the subject has now received sufficient attention. There are two chapters on ophthalmic surgery by Mr. Williamson-Noble, which will be found adequate. The surgery of the ear is in the capable hands of Mr. Watkyn-Thomas and there are eleven chapters on the surgery of the nose by Mr. Jory. In the following pages, endoscopic methods, including bronchoscopy and gastroscopy, have been fully described by Mr. Cann. On the difficult subject of malignant tumours of the pharynx and larynx, there are eight chapters by Mr. Lionel Colledge. On tonsils, adenoids and retropharyngeal abscess Mr. Charles Keogh has some interesting things to say. The surgery of the tongue, mouth and lips by Mr. Stanford Cade is worthy of note. The next part deals with the œsophagus and diaphragm by Mr. O'Shaughnessy. There is an interesting section on the mandible by Mr. Wakeley but there are three additional chapters on dental surgery by Mr. Bowdler Henry. The subject of venereal disease is discussed in two sections of which the first dealing with gonorrhœa is assigned to Dr. Malcolm Simpson. The other section, on syphilis, is contributed by Surgeon-Commander Crawford. Sir Robert Stanton Woods writes an informative chapter on physical medicine, which is assured of ready appreciation. There are three chapters on the difficult subject of deep x-ray therapy by Dr. Walter Levitt. The succeeding part by Dr. Harold Dodd deals with some aspects of general surgery. One noteworthy feature of this work, which has already been commended, is the collaboration of eminent physicians. There are seven instructive chapters on 'Some neurological and psychiatric aspects of surgery' by Dr. Rowland Hill.

In conclusion, we would like to offer our hearty congratulations to the editor on the successful completion of an ambitious undertaking. We regret that owing to exigencies of space it has not been possible to do full justice to the merits of this admirable publication. Without any exaggeration we may rightly say that there is no other book like this in the English language. We strongly recommend this book to the notice of the medical profession and the post-graduate student. The printing, get-up and illustrations are excellent and there is an exhaustive index.

P. N. R.

DISEASES OF THE EAR, THROAT AND NOSE.—
By J. Douglas McLaggan, M.A., M.B., F.R.C.S. (Eng.), and (Edn.). 1937. H. K. Lewis and Company, Limited, London. Pp. viii plus 338, with 9 plates and 135 illustrations in the text. Price, 15s.

This book is one of Messrs. Lewis's General Practice Series being intended for general practitioners and undergraduates. The author has succeeded in producing

a most useful and comprehensive work for although the title is *Disease of the Ear, Throat and Nose* there is also a chapter on diseases of the œsophagus, trachea and bronchi.

The author believes that working knowledge of the anatomy of the parts is more conducive to sound diagnosis and treatment than is a long list of drugs and proprietary preparations. As a result the book is freely illustrated with simple line drawings which emphasize clearly the various anatomical points of importance.

On the subject of tonsillectomy the author condemns entirely the use of the guillotine with a short anæsthetic, such as ethyl chloride.

This does not hold in the tropics where chloroform is such a safe anæsthetic that enucleation, with the revised guillotine is the method of choice for all children and most adults. It is then a leisurely operation and there is nothing of the 'hit or miss' order about it.

The chapter on laryngeal paralysis is lucid and well illustrated, as also is the chapter on diseases of the œsophagus, trachea and bronchi already referred to. The reproductions of the x-ray films are unusually clear.

Altogether an admirable little book which I think will become popular in that section of the profession for which it has been written.

H. S. C.

THE THYROID AND ITS DISEASES.—By J. H. Means, M.D. 1937. J. B. Lippincott Company, Philadelphia and London. Pp. xvi plus 602. Illustrated. Price, 25s. Obtainable from Messrs. Butterworth and Company (India) Limited, Calcutta. Price, Rs. 18-12

This is an excellent monograph which contains an account of the personal experiences of a large number of workers in the thyroid clinic of the Massachusetts General Hospital; their observations extend over a period of over 20 years. It will therefore be of immense value to students and practitioners not only for its wealth of information but also for its usefulness as an aid to the diagnosis and treatment of thyroid diseases. In this book, the author has always sought to gain an insight into the fundamental nature of the morbid processes responsible for the production of the clinical picture and to depend, for diagnosis and treatment, on a scientific understanding of pathogenesis. Nothing could be more commendable than this arrangement, particularly in a book on the thyroid gland.

The author has rightly devoted 3 chapters covering 100 pages to describing the anatomy and physiology of the thyroid gland. The next 3 chapters covering nearly 60 pages embody all the modern ideas about the general pathology and pathological physiology including modern methods of examination of thyroid cases. The

... deal with the detailed discussion of the clinical picture, diagnosis and treatment of the various diseases of this organ. There is one feature in this book which is extremely helpful and this is that every chapter ends with an excellent summary of the whole discussion, the perusal of which gives the reader a quick idea of the contents of the chapter. Every chapter closes with a bibliography which may not be considered as exhaustive but nevertheless is very useful. The various conditions under toxic goitre have been discussed so thoroughly that one may consider the description as the last word on the subject up to the present moment. There is a very interesting chapter at the end where the author discusses the use of the gland products in various diseases which are not of thyroid origin, and while appreciating its usefulness in these conditions he rightly sounds a note of warning by saying that the drug should never be considered as a panacea. Similarly, the question of thyroidectomy in non-thyroid diseases has also been discussed with a philosophical discourse on 'facts and fancy in matters thyroid' and this will be found to be very interesting to the reader.

It is indeed difficult to criticize a book of this nature which is an embodiment of prolonged personal experiences. There is one thing however which requires some comment and this is that the book as a whole is too good and elaborate for recommendation as a

textbook for students in general. On the contrary it is an admirable handbook for post-graduates and general practitioners in particular.

MESSAGE AND REMEDIAL EXERCISES IN MEDICAL AND SURGICAL CONDITIONS.—By M. N. D. Tidy. Third Edition. 1937. John Wright and Sons Limited, Bristol. Pp. xii plus 456. Illustrated. Price, 15s.

This is an excellent textbook for students, and reference book for practitioners. It describes practically every condition treated by massage, the principles of treatment, results to be expected and complications that may occur. It suggests allied treatments for the conditions described; and also indicates where further information about modern treatments can be obtained. The illustrations are particularly clear and instructive. The addition of the description of suspension apparatus, and a type of pulley in the treatment of patients, by Mrs. Guthrie-Smith of the Swedish Institute is most welcome. Every practical masseuse should have easy access to this book.

A PRACTICAL GUIDE TO MASSAGE.—By C. I. Carpenter. 1937. Baillière, Tindall and Cox, London. Pp. xiv plus 127, with 20 text-figures. Price, 5s.

This is a useful book to any masseuse in practice. Divided into three parts it describes how the laws of physiology govern the administration of massage, the special effects of the different movements and the conditions for which massage and allied treatments are prescribed. It emphasizes that 'the human organism must be regarded as an integral living entity in which the parts harmonize with the function of the whole, just as, inversely, the function of the smallest part is conditioned by the organism as a whole'. Carefully studied it will help the practitioner to avoid making his work mechanical.

BIOLOGICAL STANDARDIZATION.—By J. H. Burn, M.D. 1937. Oxford University Press, 1937. London. Humphrey Milford. Pp. xviii plus 288. Illustrated. Price, 21s. Obtainable from Oxford University Press, Bombay and Calcutta

Biological standardization, or the measurement of the potency of drugs by the specific reactions they produce upon intact living animals or upon surviving isolated tissues, was first used by Ehrlich to determine the strength of antitoxic sera and soon after Houghton introduced it to regulate the strength of the digitalis group of drugs. Since then, the method has gained number of importance and has been extended to a toxins, vitamin and endocrine products, organic arsenic and antimony products, synthetic antimalarial and other remedies, digitalis group of drugs, ergot and its preparations, anthelmintics, aconite, and Indian hemp. In almost all civilized countries, standardization of potent remedies is a legal obligation and workers associated with medico-legal departments are frequently called upon to give an opinion on such remedies. Prof. Burn's first book *Methods of Biological Assay* was too small and embraced only a limited field of drug-standardization work. A more elaborate treatise from the pen of such an eminent authority was therefore keenly awaited. Such a treatise is now brought out by Prof. Burn and there is little doubt that the book will meet with a tremendous welcome from pharmacologists in all parts of the world. The book is divided into 19 chapters of which the first two are concerned with the statement of introductory principles and the different methods of calculation

M. N. D.

of the minimum lethal dose. The third chapter discusses statistical methods of interpreting experimental results and gives formulae to be used in determining the accuracy and adequacy of experimental findings. Prof. Burn has an enviable way of presenting abstruse scientific data in simple language and in no chapter is this more exemplified than in his mathematical treatment of results. Those who have laboured hopelessly with authoritative books on statistical analysis will have ample reason to be grateful to him for this chapter. In chapters IV to XIX are described the most serviceable methods of standardizing the various therapeutic agents. Pertinent details are given, illustrated whenever necessary with charts, tables, and diagrams, but dilatory techniques are judiciously avoided. Several recent methods developed in his own laboratory, *e.g.*, standardization of adrenal cortical hormone on drakes, potency test of organic arsenicals and antimonials by noting the survival time in mice, and the anti-diuretic method of posterior pituitary assay, are described in detail; these are likely to prove very useful and time-saving. In the assay of thyroid extracts and time-preparations, both chemical and biological assays are given, as the chemical assays with regard to these are gradually being more widely adopted.

The book describes all that is needed for pharmacologists engaged in drug assays in governmental, public health or commercial organizations. It is too technical for students in medical schools and colleges but those who are responsible for teaching and colleges but those themselves abreast of the modern developments in this domain of quantitative pharmacology by reading this excellent book. The reviewer only feels that the utility of the book would have been still further enhanced had the author included an account of the standardization of sera, vaccines, antigens, etc. The author probably had good reasons for not including such a chapter but there is no gainsaying the fact that there is demand for an authoritative publication in this field also. The book is well got up and handy, the binding and format are excellent, and the diagrams are well executed. No modern pharmacological or physiological laboratory should be without a copy.

SEX IN RELATION TO SOCIETY.—By B. M. Ellis. 1937. William Heinemann (Medical Books) Limited, London. Pp. xv plus 529. Price, 12s. 6d.

This is an abridged and revised edition of volume VI of the original series 'Studies in the Psychology of Sex', so it is really the first English edition of the book. When first published this book was almost unique of its kind but in the thirty years since its first appearance there has been a very great change in the attitude of the lay public and of the medical profession so that matters pertaining to sex are now frankly discussed and written about. The consequence is that there has been a glut of books of this nature by qualified and unqualified authors. In spite of this keen competition we consider this book will hold its own for it appeals to us as the best exposition we have read of this subject. This is only to be expected for the author has devoted practically the whole of a long life to the study of the subject of sex problems of which he is such a noted exponent. It can be recommended to both medical and non-medical readers as a book well worth studying.

TREATMENT OF SOME CHRONIC AND 'INCURABLE' DISEASES.—By A. T. Todd, O.B.E., M.B. (Edn.), M.R.C.P. (Lond.). 1937. John Wright and Sons, Limited, Bristol. Pp. viii plus 203. Price, 10s.

In this volume Dr. Todd deals with a number of diseases the current therapy of which is either unsatisfactory or completely ineffective. In order to influence favourably the outlook be dropped, and the anatomical diagnosis or outlook of some part of the patient be examined for dysfunctions of which, if possible, may of the body, the correction of which, if possible, may by chance lead to recovery. Many different diseases

have been ascribed to the same event or cause. For example, chronic nasal sepsis is found to induce asthma, bronchitis, false phthisis, emphysema, rheumatism and nephritis. Duodenal infection is found to produce hepatic dysfunction, chronic rheumatism, false heart disease, cholecystitis, etc. Unfortunately many of these chronic and 'incurable' diseases are very complex processes and are not amenable to simple or rapid therapeutics. The author however has described certain effective procedures which are worth a trial in spite of the fact that some are slow and rather difficult to carry on.

Diabetes mellitus has been considered as a disease in which the liver is chiefly involved, rather than the pancreas, and ordinarily the author has obtained better results with synthalin and bile salts than with insulin. The ketogenic diet is not advised in epilepsy, as it is intolerable to the majority of patients. The use of liquid paraffin in chronic constipation has been deprecated as it is said to depress the hepatic function, increase flatulence and occasionally give rise to giddiness. This appears to be very hypothetical; it would be safer and wiser to encourage its use and stop the abuse of various purgatives.

R. C.

CIVILIZATION AND DISEASE.—By C. P. Donnlson, M.D. (Lond.), M.R.C.P. (Lond.). 1937. Baillière, Tindall and Cox, London. Pp. xv plus 222. Price, 10s. 6d.

THIS is a speculative book on the subject of the different distribution of certain diseases among civilized and uncivilized races. The data of practically all the diseases discussed are admittedly inadequate; this is well shown by quoting the summary of chapter two of the book itself.

'A survey of the incidence of diseases in different races with a view to ascertaining the relationship between disease and civilization can be summarized in the following tables:—

I. Diseases that show a close relationship with civilization.

Hyperpiesia.	Diabetes mellitus.
Graves's disease.	Peptic ulcer.
Psychoneurosis.	Rickets.
	Obesity.

II. Diseases that appear to show some relationship with civilization but in which the evidence is anomalous or inadequate to justify a definite conclusion.

Cardio-vascular syphilis.	Schizophrenia.
Neuro-syphilis.	Gall stones.
Acute pyelitis and cystitis.	Appendicitis.
Uterine fibro-myomata.	Enlarged prostate.
Pernicious anæmia.	Toxæmias of pregnancy
Angina pectoris.	Renal calculus.
Dental caries.	Coronary thrombosis.
Myxœdema.	Enlarged tonsils and adenoids.
	Manic-depressive psychosis.

In the reviewer's opinion all the diseases might be placed in group II as the evidence produced for all of them is hardly complete enough yet.

As it stands the book is of little practical use but it may serve its purpose in drawing the attention of other workers to the subject and thus it may become the foundation for more exact knowledge.

MEDICAL RESEARCH COUNCIL. SPECIAL REPORT SERIES, NO. 223. SOME QUANTITATIVE ASPECTS OF THE BIOLOGICAL ACTION OF X AND γ RAYS. By C. M. Scott. 1937. Published by His Majesty's Stationery Office, London. Pp. 99. Illustrated. Price, 1s. 6d.

'THE remarkable progress made during the last decade in the treatment of cancer and malignant disease by radium and high voltage x-rays is a matter of general knowledge.

The very rapidity of these advances, however, has caused the practical application to outstrip scientific knowledge; in consequence the therapeutic use of radiations is to a large extent empirical, since there is no basis of agreed fact regarding the essential mode of action of radiations on cells.

One of the chief points brought out by this report is the extraordinary variation which living cells display as regards susceptibility to radiation. It is shown, for example, that the irradiation needed to kill the adult fruit-fly (*Drosophila*) is several thousands of times that needed to kill the eggs of the fly. Translated into terms of drug dosage this would mean that an animal at one stage of its existence was killed by a milligramme of some drug and at a later stage was killed only when the dose amounted to several grammes. The general argument running through the report is that any explanation of the mode of action of radiations on cells must take into account this extraordinary variation in sensitivity, and many attractive theories regarding the action of radiations break down in face of this difficulty. For example, radiations have been shown to interfere with various forms of cellular metabolism and this suggests a possible manner in which they might kill radio-sensitive cells. Such an hypothesis, however, is obviously unsatisfactory unless it explains why radiations have little or no action on other cells with a metabolic mechanism similar to that of the sensitive cells.

The evidence marshalled by the author of the report is in favour of the view that the fundamental action of radiations is on the nucleus of the cell, and thereby on the cell processes that control growth. Hence, the susceptibility of cells to radiation depends very largely upon whether their survival is dependent on the power to carry out cell division.'

CORRIGENDUM

ON p. 55 of our January 1938 issue in the review on 'Wheeler and Jack's Handbook of Medicine' the name of the reviser is John Henderson, not John Anderson as stated in this review.

Abstracts from Reports

ANNUAL REPORT OF THE ALL-INDIA INSTITUTE OF HYGIENE AND PUBLIC HEALTH, 1936.

PUBLIC HEALTH RESEARCH

DETAILS of research and investigations bearing on public health problems were given in the annual report of the All-India Institute of Hygiene and Public Health.

Intensive statistical analysis of recorded cholera mortality in different parts of Bengal, the home of cholera, has shown that the incidence of the disease is not uniform throughout the province. It has, however, been possible to define certain areas which are highly

endemic. In one of these areas continuous field observations were carried out and a large amount of information collected, the analysis of which, it is hoped, will clear up certain important points in regard to the cholera problem.

Statistical studies were also carried out with a view to developing a method of forecasting cholera epidemics, in order to forewarn public health authorities. In addition, there were basic researches into the chemical constitution of cholera germs in relation to the virulence of the organism, and important results have been obtained.

Epidemic dropsy is another disease which received special attention. Field investigations carried out in

THE ANNUAL REPORT OF THE PUBLIC HEALTH CIRCLE OF THE PUBLIC WORKS DEPARTMENT, BIHAR, FOR THE YEAR 1935-36

Assam, Bengal and Bihar indicated that certain samples of mustard oil may be to blame. As a result of a series of control experiments, including experiments on human volunteers, it is emphasized that certain supplies of mustard oil contain a substance which may be responsible for the production of symptoms of epidemic dropsy. The problem is as yet by no means solved.

Problems of nutrition, which are attracting more and more general attention, were also investigated. A large number of common Indian foodstuffs were examined for their salt and vitamin contents, particular attention being given to vitamin B. Nutrition surveys for the determination of the quantity and quality of food and nutritional status of children were carried out in certain institutions at Calcutta and at Ferozepore in the Punjab.

It was found that the main deficiency in diet was the lack of good types of protein and of certain salts, and that this defect in the dietary, which could be corrected by milk, had much to do with the poor physique of children. The calorie value of food required by Indian children was found to be the same as that required by English children.

A fact of great importance which emerged was the desirability of combining fat and, if possible, meat with food containing green vegetables and carrots. These foodstuffs are rich in the substance carotene, which is the main source of vitamin A in India, while fat helps in the absorption of carotene and meat in its conversion into vitamin A.

In the malaria section attention was chiefly devoted to investigations into blackwater fever, which occurs in certain highly malarious localities. Blackwater fever is a highly fatal affliction, but unfortunately there is still uncertainty as to the exact cause and treatment. Studies of similar conditions in monkeys show that it was caused by paucity of the balance of certain chemical constituents of blood due to lesions in the liver and the adrenal glands. A partial success in the treatment of the disease was on these findings obtained by basing treatment on these findings.

Investigation of the disease was extended to human cases and promising results were obtained. Other malaria problems studied included investigations into the part played by certain important malaria-carrying species of mosquitoes and the spread of malaria in Bengal and certain basic studies on malaria parasites.

Among the points brought out in the study during the year of tuberculosis was the danger from exposure of contacts, especially of children, to open cases in the family.

It was found that in 94 per cent of deaths due directly to childbearing, a primary avoidable factor was present, the main causes of maternal deaths being due to infection arising out of uncleanness during childbirth, poison in the system and accidents of labour.

The institute among other activities provides advanced training for public health workers on an all-India basis. Admission has to be restricted to 30 students on account of limited laboratory accommodation. In previous years some of the seats remained vacant, but a noticeable feature of the year under report was that there were 74 applicants.

The institute was established with funds provided by a donation of Rs. 17.87 lakhs from the Rockefeller Foundation of the United States of America. The responsibility for its maintenance has been undertaken by the Government of India. Unfortunately the opening of the institute coincided with a period of acute financial stringency, and thus the full development originally contemplated has had to be deferred. As a result, while four sections dealing with Public Health Administration, Malariology, Biochemistry, Nutrition and Epidemiology and Vital Statistics have been functioning, two sections on Sanitary Engineering and Maternity and Child Welfare have had to be kept in abeyance. With a return to improved financial conditions, the Government of India have, as from April 1937, sanctioned the opening of these two new sections.

Of the more important works taken up by the superintending engineer at Government expense mention may be made of water-supply to the new district headquarters at Luthaha. Besides this, another project of no less importance was in contemplation, viz., to provide internal water-supply and sanitary installation in the proposed blocks consisting of an additional ward at Itki Sannatorium, for 31 patients. Of the various other works undertaken on behalf of the various local bodies the Bhagalpur water-supply reorganization scheme amounting to Rs. 5,10,974 still continued to occupy the most important place. Work on the distribution system was completed and satisfactory progress was made with the new intake well at Barari.

Among other works in the hands of the department mention may be made of the water-supply reorganization schemes of Muzaffarpur and Monghyr. The remaining work of fixing house service meters in the reorganization scheme of Muzaffarpur supply was completed. The total expenditure and the expenditure during the year were Rs. 1,86,028 and Rs. 5,569 respectively. The execution of the work in the reorganization scheme of Monghyr water-supply amounting to Rs. 82,039 containing provision for new filtered water and unfiltered water pumping plant, etc., was delayed because an agreement between the Municipality and the Electric Supply Company for the supply of electric power to the proposed new pumping plant had not been executed.

The superintending engineer continued to take the same care and attention as in previous years, to the inspection and supervision of all the existing municipal waterworks in the province which were maintained at a total cost of Rs. 3.74 lakhs compared with Rs. 5.59 lakhs in the preceding year. It is satisfactory to note that a fair standard of efficiency was attained. Twenty-one Government pumping plants and sanitary installations were maintained by the circle during the year.

Correspondence

A CRYING NEED FOR A PHARMACY ACT IN INDIA

Sir,—The Drugs Enquiry Committee was appointed by the Government of India in the year 1930; among others, eminent pharmacologists like Col. R. N. Chopra, I.M.S., and Rev. Father Caius served on the committee. The report was submitted to the Government of India in the year 1931. There can be absolutely no doubt that the opinion on drugs and pharmacy given by such persons is authoritative and it is no wonder that the recommendations of the said committee were recognized by one and all to be very valuable. Now it strikes me why the Government of India is sleeping over the report for the last seven years, specially on the question of education and control of pharmacists, while the committee was appointed by the Government of India at their own initiative and the Government of India so valuable and heavy amount of public money was spent for the report.

There are indications that sporadic attempts are being made to implement some of the recommendations, but the fundamental thing is that no serious attempt is being made to put the recommendations of the committee into effect.

Although the provincial autonomy under the Government of India Act, 1935, was not introduced until six years after the publication of the report, the Central

Government all along tried to avoid the responsibility of implementing the recommendations on the plea that they are mainly provincial matters and as such any interference by the Central Government will be undesirable. They, therefore, shelved the matter all these years giving laconical replies to insistent public demands. Tone of the Government reply was practically always the same, 'The matter is under examination, but the recommendations are mainly provincial subjects', etc.

In the meantime commercial bodies and the public press of India without any distinction of party did not relax their pressure on the Government to give effect to the recommendations of the committee. The Unemployment Committee appointed by the U. P. Government with the Rt. Hon'ble Sir Tej Bahadur Sapru as president for a solution of the unemployment problem recommended among others to organize the profession of Pharmacy as suggested by Col. R. N. Chopra Committee which will throw new avenues to unemployed youths in the country. One cannot think what is still left for the Government of India to examine for all these years when the soundness of the recommendations has been acknowledged by such eminent authorities like Rt. Hon'ble Sir Tej Bahadur Sapru, Col. Chopra, Col. Gidney and other eminent persons.

We might have difference of opinion with regard to communal representation in the legislatures and other public matters, but in the matter of implementing the recommendations of the Drugs Enquiry Committee, the commercial bodies, the Hindus and the Moslems, majorities and minorities, congress and non-congress and the public press are unanimous without any distinction of caste, creed or party. The Government, therefore, cannot say by any stretch of imagination that if a particular recommendation of the committee be given effect to that would wound the religious feeling of any particular community or party.

The recommendations, if duly implemented will raise the economic status of the people and will bring well-being of the people in general without any caste, creed or party. If anybody is to suffer as a result of giving effect to the same there will be a very small group of people who indulge in nefarious practice of playing on human life with disastrous results, the only aim of the group of these people is to fill up their pockets without any regard to morality. Surely the Government will not hold brief for this class of people. Nothing can therefore stand in the way of the Government in implementing the recommendations particularly as regards the organization of the profession of pharmacy, the crying need of which is now felt more than ever.

Now from the statement of the objects and reasons published with the Import of Drugs Bill recently introduced in the Indian Legislative Assembly we find that the Government of India has taken another dilatory tactic for shelving the matter further. The control of import of drugs is one of many recommendations of the Drugs Enquiry Committee. The Government of India has said that other recommendations such as manufacture, storage and sale of drugs, education and control of pharmacists have been left for the provincial Governments to deal with. It is further understood that the Director-General, Indian Medical Service, has drafted a bill which is under examination of the Government of India dealing with above-mentioned matters now left by the Central Government for the provincial Governments to deal with. This is a clever way of shelving the matter. Now the provincial Governments will have their turn to say from time to time for another decade in reply to the public demands that 'they are examining the bill', they are consulting public bodies', etc. To show how much cold are the provincial Governments in the matter of pharmacy, I shall cite only one instance. The State Medical Faculty of Bengal, the president of which body is the surgeon-general himself and which body at present controls the professions of medicine and pharmacy, approved in February 1934 on the recommendation of the sub-committee appointed by itself, the syllabus for the training of the compounders, as

suggested in the Drugs Enquiry Committee's report and forwarded the same to the Government of Bengal for final approval, but in course of these four years neither any reply could be obtained from the Government nor any communicate has been issued by the Government and the public are still in the dark about the said proposal of the Faculty.

This matter has been examined enough and enough consultation has been made and there is no reason on the earth if the Government intention be frank to take steps for implementing one recommendation by the Central Government and leave the others for provincial Governments. If all the recommendations are given effect to by the same enactment by the Central Government the obvious advantage will be that uniformity will be observed in all provinces and the matter will be expedited.

The Drugs Enquiry Committee has also examined the question very carefully and thoroughly as to whether its recommendation should be implemented by single enactment or by piece-meal legislation, whether some of the recommendations should be dealt with by the Central Government and others by the provincial Governments and their unanimous opinion was that the recommendations should be implemented by single enactment and that too by the Central Government alone.

Considering all these it is fair and reasonable that the Government of India should immediately undertake the legislation in the matter in full, instead of leaving a part for the provincial Governments. Moreover, when the bill as drafted by the Director-General, Indian Medical Service, relating to pharmacy and the bill for the control of import of drugs are now at the disposal of the Government of India, with a little additional labour a comprehensive bill comprising all the recommendations of the committee can be placed before the Indian Legislative Assembly.

Yours, etc.,
KARUNA KUMAR ACHARJEE,
Vice-President,
Bengal Pharmaceutical Association.

MAKARDAH CHARITABLE
DISPENSARY,
P. O. MAKARDAH.
HOWRAH,
8th December, 1937.

[Note.—This letter is a little difficult to follow in places, and we do not feel able to 'edit' it. We are, however, in sympathy with the writer's main argument.—
EDITOR, I. M. G.]

QUININE TOLERANCE IN PREGNANCY

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—The above article in the December 1937 issue interested me very much because it raises some other points. The patient was given nine 10-grain quinine injections intramuscularly, thrice daily and on consecutive days. In the London School of Tropical Medicine and Hygiene they condemn most emphatically intramuscular injections of quinine. They say quinine causes tissue necrosis, much of the quinine remains unabsorbed, at least for a very long time, because of the necrosis the site remains painful, occasionally tetanus develops and abscess formation is fairly frequent. They teach that if quinine is to be given parenterally, it must be given intravenously.

I presume, all the injections were given intragluteally. It would be interesting to know what was the attitude of the patient towards the injections. I have no experience in this method, because, knowing that it is painful, I always use intravenous method whenever quinine by injections is indicated; I guess, however, that it would be difficult to find ten painless sites in such a short period.

In the particular case, when it was decided to give quinine parenterally and when evidently quick result rather than a slow and prolonged effect was required,

I wonder why intramuscular instead of intravenous route was chosen and that too all through.

Yours, etc.,

RAJANINATH R. GHAREKHAN,

M.B., B.S., L.M., D.T.M. & H.,

Medical Officer.

BARODA STATE,

DABHOI,

30th December, 1937.

[Note.—We are in almost complete agreement with our correspondent.

Ninety-nine times out of a hundred administration of quinine by the oral route is adequate, and in the hundredth case the intravenous route is, in our opinion, preferable to the intramuscular. Circumstance may demand one and possibly a second dose of parenteral quinine, but any circumstances that demand an extended course of intramuscular quinine are unconnected with the treatment of malaria.

On the other hand, many conscientious and intelligent practitioners give quinine by the intramuscular route frequently, and do not get bad results. Injections of quinine undoubtedly cause necrosis of the tissues, but such a condition is not necessarily dangerous and may even be advantageous. The statement that quinine given intramuscularly in ordinary clinical doses may not be absorbed requires to be proved; certain experiments on which this claim is based did not, in our opinion, supply this proof.—EDITOR, *I. M. G.*]

Service Notes

APPOINTMENTS AND TRANSFERS

BREVET-COLONEL R. N. CHOPRA, C.I.E., Professor of Pharmacology, School of Tropical Medicine, Calcutta, is confirmed as Director of the same institution, with effect from 8th August, 1935.

Lieutenant-Colonel Amir Chand, Officiating Professor of Medicine, King Edward Medical College, Lahore, has been confirmed in his appointment, with effect from 1st March, 1937.

Lieutenant-Colonel J. C. Pyper has been posted as Civil Surgeon, Quetta. Dated 1st November, 1937.

Lieutenant-Colonel R. H. Candy, C.I.E., on return from leave, has been appointed as Civil Surgeon, Poona, with attached duties, with effect from 10th November, 1937, afternoon.

Lieutenant-Colonel F. R. Thornton, Civil Surgeon, Poona, on relief by Lieutenant-Colonel R. H. Candy, has been appointed as Civil Surgeon, Dharwar, with attached duties, with effect from 19th November, 1937.

On return from leave Lieutenant-Colonel M. Das, M.C., is appointed to be Superintendent of the Alipore Central Jail, with effect from the forenoon of the 19th November, 1937, *vice* Major S. Annaswami transferred.

Lieutenant-Colonel J. P. Canteenwalla took over charge of the Medical Store Depot, Calcutta, on 22nd November, 1937.

Lieutenant-Colonel R. Sweet, D.S.O., took over charge of the Medical Store Depot, Bombay, on 24th November, 1937.

Lieutenant-Colonel S. Nag made over charge of the Mymensingh Jail to Lieutenant-Colonel B. H. Singh, on the forenoon of 24th November, 1937.

Lieutenant-Colonel A. Ba Thaw appointed as Assistant Inspector-General of Civil Hospitals, Burma. Dated 11th December, 1937.

Lieutenant-Colonel R. H. Malone, Pathologist, Rangoon General Hospital, appointed to hold full charge of the duties of the Director, Pasteur Institute of Burma, Rangoon, in addition to his own. Dated 14th December, 1937.

Major G. F. Taylor, Officiating Professor of Clinical Medicine King Edward Medical College, Lahore, has

been confirmed in his appointment, with effect from 1st March, 1937.

Major T. Doran, on return from leave, has been posted as Civil Surgeon, Belgaum, with effect from 15th October, 1937.

Major C. K. Lakshmanan appointed as Port Health Officer, Calcutta, with effect from the afternoon of 16th October, 1937.

Major E. M. Sewell, transferred from the Military Department to Madras Civil, will be deemed to have been on reserve duty in the Government General Hospital, Madras, from 15th November, 1937, to 17th November, 1937 (afternoon), and then posted to act as District Medical Officer, Bellary, with effect from the date of taking charge.

Major P. A. C. Davenport appointed as Civil Surgeon, Toungoo. Dated 4th December, 1937.

Major S. Annaswami, Officiating Superintendent, Alipore Central Jail, on being relieved of his charge by Lieutenant-Colonel M. Das, M.C., in the forenoon of 19th November, 1937, is appointed to act as Superintendent of the Midnapore Central Jail.

Major Gerard Kelly, on the expiry of his leave, is appointed as First Resident Medical Officer, Presidency General Hospital, Calcutta, *vice* Captain E. H. Lossing.

Captain W. W. Laughland has been appointed to officiate as Superintendent, Central Mental Hospital, Yeravda, with effect from 1st October, 1937, *vice* Lieutenant-Colonel E. C. A. Smith, granted leave.

Captain M. H. Shah is appointed as a leave reserve officer to the Irwin Hospital, Delhi. Dated 16th October, 1937.

Captain J. D. Grant has been posted as Civil Surgeon, Sibi and Loralai. Dated 15th November, 1937.

Captain M. Jaffar is appointed to officiate as Health Officer, Karachi Air Port. Dated 16th November, 1937.

Captain A. A. Pullar, Assistant to the Civil Surgeon, Poona, has been appointed to officiate as Presidency Surgeon, Bombay, with effect from 6th December, 1937, *vice* Captain H. S. Waters, granted leave.

Captain H. Min Sein is appointed as Civil Surgeon, Bassein. Dated 8th December, 1937.

Captain A. K. Gupta made over charge of the Berhampore Jail to Dr. B. N. Chakravarti in the afternoon of 6th December, 1937.

Captain E. H. Lossing, First Resident Medical Officer, Presidency General Hospital, Calcutta, on relief, is posted to Hooghly as Civil Surgeon, *vice* Dr. Jatindra Mohan Mukharji.

To be Lieutenants (on probation)

1st November, 1937

Thomas Menrig Williams, with seniority from 1st May, 1936.

Robert Dennis Ewing, with seniority from 1st November, 1936.

Patrick Bernard Cusack, with seniority from 1st November, 1936.

Thomas Patrick Binns, with seniority from 26th March, 1937.

William Walter Coppinger, with seniority from 1st May, 1937.

Richard Douglas Davis Birdwood.

John Murray Drew.

The undermentioned officers are restored to the establishment

1st November, 1937

Lieutenant N. P. Woodgate-Jones.

Lieutenant W. H. A. Thorne.

LEAVE

The portion of leave from the 19th November, 1937, to 9th January, 1928, out of the 7 months' leave granted to Lieutenant-Colonel M. Das in previous notification, is hereby cancelled.

Lieutenant-Colonel G. C. Maitra is granted leave for 3 months from 14th December, 1937.

Major W. Aitchison, M.C., Civil Surgeon, Cawnpore, is granted leave for 4 months from 4th December, 1937.

Major D. MacD. Fraser, Civil Surgeon, Dehra Dun, is granted leave for 4 months from 1st December, 1937.

Major R. A. Wesson, Civil Surgeon, Moradabad, is granted 8 months' leave from 3rd January, 1938, with permission to prefix the Christmas holidays.

Major K. S. Fitch, Civil Surgeon, is granted leave for 10 months, with effect from 10th November, 1937.

Captain D. K. L. Lindsay is granted leave on average pay for 4 months, study leave for 5 months and furlough for 1 month from 27th November, 1937.

Captain H. S. Waters, Presidency Surgeon, Bombay, is granted leave ex-India on average pay for 8 months combined with leave on half average pay for 3 months, with effect from 4th December, 1937.

PROMOTIONS

Major to be Lieutenant-Colonel

J. H. Barrett. Dated 2nd November, 1937.

Captains to be Majors

R. M. Lloyd Still. Dated 1st April, 1937.

L. G. Buekhurst. Dated 10th November, 1937.

D. C. Chopra. Dated 19th November, 1937.

Jaswant Singh. Dated 19th November, 1937.

P. P. Chowdry. Dated 22nd November, 1937.

P. C. Dutta. Dated 25th November, 1937.

Lieutenants to be Captains

J. R. Kerr. Dated 8th October, 1937, with seniority from 1st May, 1937.

K. I. E. Macleod. Dated 8th October, 1937, with seniority from 1st May, 1937.

J. D. Munroe. Dated 8th October, 1937, with seniority from 1st May, 1937.

J. H. Walters. Dated 7th October, 1937, with seniority from 1st November, 1936.

C. F. Mayo-Smith. Dated 9th October, 1937, with seniority from 1st May, 1937.

W. C. Templeton. Dated 8th October, 1937, with seniority from 1st May, 1937.

Notes

ANNOUNCEMENT

A NEW lecture room has been opened in the office premises of the Haverro Trading Company at Bombay. The opening ceremony was performed by Lieut.-Colonel S. S. Vazifdar on 19th December, 1937, before a distinguished gathering of the medical profession of Bombay.

In welcoming the guests, Dr. K. Soltner, Ph.D. (Berlin), emphasized the long-felt demand for such a lecture room in our establishment at Bombay. Now that the long-cherished wish has been consummated, he hoped that this room would henceforward serve as a common platform for more effective interchange of opinions and scientific findings between the clinicians of this country and the research workers of the 'Bayer' laboratories in Germany.

Lieut.-Colonel Vazifdar in his presidential address gave a short but impressive outline of the history of evolution of chemotherapeutic drugs and exhorted the audience to ponder over the real significance to suffering humanity of the discovery of drugs like 'Bayer' 205, salvarsan, atabrin and plasmochin, protosil, etc. Finally, he emphasized the need of Indian collaboration in the forward march of scientific therapy in the growth of which 'Bayer' laboratories have done so much during its fifty years of existence.

After a light tea, a scientific film on 'Circulation' was screened. The function ended with a vote of thanks to the guests and the president from Dr. Soltner on behalf of Messrs. Haverro Trading Company Limited, as well as the research workers in 'Bayer' laboratories.

O-R-95 (THROAT TABLETS)

O-R-95 is unusually effective in controlling bacterial infections, inflammation and painful conditions of the mouth, tongue, gums, soft palate, tonsils, nasopharynx and hypopharynx, introitus of the larynx and oesophagus. Quinsy, laryngitis and pharyngitis respond promptly to the action of O-R-95. Sore throat and tonsillitis may be checked at the onset by its use.

In chronic coughing spasms, irritating coughs, and in posterior nasal drips, O-R-95 soothes the irritation promptly and efficiently, because of its direct action upon the nerve endings within the pharyngeal and glottis mucosa.

One tablet should be sucked slowly in the mouth every 3 hours or oftener if necessary. The tablet should not be chewed, but allowed to dissolve slowly, in order that the medication will mix thoroughly with the saliva before swallowing. When swallowing is very painful, it is advisable to take two tablets $\frac{1}{2}$ hour before meals. Before laryngoscopy, tonsillectomy, or other operations in the mouth two tablets may be sucked at once.

Chemical description.—O-R-95 tablets (Ethyl-butyl-ester of di-amido-di-ethyl-amido-ethyl-carbamido dicarboxy-di-phenyl-methane-aeridino-oxyquinoline) contain a newly-synthesized uniform chemical compound, a neutral crystalline, water-soluble substance that is odourless, and of slightly bitter taste. This compound is stable in all solvents, resists boiling and is not precipitated by salines, serums or proteins; it is combined with a number of known adjuvants such as borax, potassium sulphate and benzocaine.

Messrs. Coates and Cooper, Limited, 94, Clerkenwell Road, London, E.C.1, are the agents in Great Britain.

Publishers' Notice.

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to 'The Indian Medical Gazette', Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers (if available) for the previous year Rs. 2-8 each, and all other back numbers Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, nor creased, in transit.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

ON THE ILLUSTRATION OF THE RHEUMATIC PROCESSES IN A MODERN MUSEUM OF PATHOLOGY

(A PAPER TO ILLUSTRATE HOW PATHOLOGICAL PROCESSES CAN BE CORRELATED WITH THE CLINICAL STAGES THROUGH WHICH DISEASES OFTEN PASS AND AS MAY BE EXEMPLIFIED BY THE EIGHT CLINICAL STAGES THROUGH WHICH RHEUMATIC INFECTION OFTEN PROGRESSES IN YOUNG INDIANS)

By H. STOTT, M.D., F.R.C.P., D.P.H.

LIEUTENANT-COLONEL, I.M.S.

Professor of Pathology and Physician, King George's Hospital, and Dean of the Medical Faculty, Lucknow

Introduction: The stages of progressive disease

A DEFINITE advance in the teaching of 'disease' to medical students during the past two or three decades has been an emphasis on the fact that disease is not an isolated static condition—as so often suggested by a 'meat' specimen mounted in a pathology museum—but that it is a *progressive* pathological process. A disease process should be visualized as arising under a variety of predisposing and causative conditions often terminating in resolution and recovery. But not infrequently the process progresses through a series of stages extending perhaps over several years to a permanent healed scar which may subsequently cause mechanical failure in the structure concerned.

It is stimulating to the student, and to the teacher, to form a clear mental picture of each of these various clinical stages. And, further, to determine in which stage any given clinical case that is before them may be classed. In such a case, evidence may be found in the patient's history of the previous stages through which his disease has already developed, and the possible or probable further stages through which the process may be expected to travel can be forecast. Finally, with each clinical stage the laboratory and post-mortem findings can be correlated. Every case of a given disease does not of course invariably progress through the complete series of stages into which that disease may be in general divided; such divisions are artificial. Any given case may exhibit a fulminating, acute, subacute or more chronic development. Any one stage or stages may not be apparent—and may progress insidiously entirely unobserved by the patient. The disease may thus appear to arise in its third, fourth or fifth stage. Or one or two or even more stages may be combined and obvious at the same time. Nevertheless, the general rule holds true that most diseases do progress through fairly well-defined stages, which can be recognized and separated from each other by clinical symptoms,

signs, instrumental investigations, laboratory and radiological tests and by post-mortem examination. As has been already remarked the recognition of such stages is stimulating; it carries the teacher and the taught back to predisposing and exciting causes, and thus to a consideration of the important aspect of prevention. It renders the diagnosis more accurate, the treatment applied more appropriate, the prognosis truer, the prevention of relapse or of sequelæ more intelligible, and the general advice offered as to the patient's conduct of life sounder.

It has been my endeavour, at the bedside, in the lecture room, in the laboratory, in the dead house and also by the construction of a special division of the King George's Medical College Museum of Pathology (division V: 'Disease processes in separate diseases') to emphasize such a system of teaching to the students entrusted to my care.

The scope of this paper

The present paper illustrates this general proposition concerning the progressive stages of disease by describing those particular clinical stages through which one disease, rheumatic infection, is apt to progress. In the paper's subtitle the words 'in young Indians' might be taken to indicate that stages in them differ from those 'in young Europeans'. But this is not the case. These words have been added to emphasize that rheumatic infection does occur and indeed is by no means uncommon 'in Indians'—and further that such infection commonly occurs in Indian juveniles and the sequelæ in young Indian adults. Thus, an emphasis lies on the well-recognized fact that rheumatic infection is mainly a condition of childhood, of youth and of young adults. To those who are aware of the fallacious way in which the civil hospital statistics of India often show acute muscle and joint pains with or without fever, in persons of 40 or 50 years of age as acute rheumatic infection, such emphasis will not be regarded as redundant.

This paper further deals briefly with the illustration of the clinical stages as of one disease (rheumatic infection) correlated with the pathological processes of one given disease (acute rheumatic infection) in a modern museum of pathology. Such illustration will be made clearer by photographs of the exhibits of this disease process in the King George's Medical College Museum of Pathology. The exhibit is not meant to be complete in every detail but illustrates the manner in which the stages of disease processes may be taught in the wards, and may be visually demonstrated by specimens in a 'living' museum of pathology.

The illustration in King George's Medical College Museum of Pathology of the pathological and clinical process of separate diseases

One division (V) of our pathological museum is entirely concerned with the correlation of

pathological processes with clinical signs in the several stages of individual diseases. So far some 16 diseases have been thus illustrated grouped in the following manner:—

Division V: Pathological processes in separate diseases, correlated with their clinical signs

V¹. *Of the inflammatory group.*

- A. Rheumatic carditis.
- B. Acquired syphilis (arteriolitis).
- C. Glomerulo-tubular nephritis.

V². *Of the degenerative group.*

- D. Hepatic cirrhosis.
- E. Arteriosclerosis.
- F. Atheroma.
- G. Ankylostomiasis.

V³. *Of the metabolic group.*

- H. The acute diabetes of the young.
- I. The chronic diabetes of older persons.
- J. Gastro-duodenal ulcer.

V⁴. *Of the psychological group.*

- K. Manic depressive insanity.

V⁵. *Of tumour growth.*

- L. Gastric adeno-carcinoma.

V⁶. *Of immunological reactions to infection.*

- M. Typhoid fever.
- N. Relapsing fever.
- O. Typhus fever.
- P. Pneumonia.

It would render all museums of pathology of far greater 'living' value and of far greater practical utility if a division showing such pathological processes in individual diseases were introduced, and further if as large a number as possible of diseases were illustrated in this manner.

The eight clinical stages through which rheumatic infection often progresses

It is my custom to describe and teach the following clinical stages of this infection:—

	Clinical stages.	Approximate duration
Stage	I. Tonsillitis. Damp chills	Few days.
Stage	II. Quiescent ..	Few weeks.
Stage	III. Acute rheumatic endocarditis.	1 to 2 months.
Stage	IV. Symptomless ..	Few years.
Stage	V. Effort syndrome ..	Few years.
Stage	VI. Auricular fibrillation ..	Months or years.
Stage	VII. Tricuspid regurgitation and cardiac cedema. }	
Stage	VIII. Slow death and post-mortem.	—

These stages might be summarized in the following progressive clinical history: a young child, debilitated perhaps from ill-nourishment or from severe ankylostomiasis or malarial anæmia, living perhaps in damp surroundings

round a damp dwelling exposed to monsoon rains or to wetting from water during his work (e.g., *dhobies*), subject to chills from monsoon or cold night winds or even from the draughts of bad ventilation or even from punkas, contracts recurrent sore throat and subacute tonsillitis. After several relapses of this condition the tonsillitis becomes quiescent but flares up, possibly after exposure to a damp chill, into fever and acute or subacute rheumatic endocarditis—possibly with exquisitely tender and painful joints—from which the pains and swelling rapidly pass to other joints. After a few months' convalescence the child passes into a symptomless stage when it has apparently completely recovered. During this time, however, the inflamed fibrous tissue around the ring of the mitral valve gradually contracts down to a firm organized scar tissue producing obvious signs of mitral stenosis. A more acute, more intense inflammation of the mitral valve will result in its acute destruction with the production of mitral regurgitation rather than of mitral stenosis. During this period the preceding tonsillitis, febrile carditis, and joint pains and swellings are forgotten. Dyspnoea on exertion gradually develops—at first hardly noticed but later becoming more and more incapacitating—until the patient becomes completely bedridden with auricular fibrillation or congestive heart failure. The admission is now made for heart failure from mitral valve disease. After relief by rest and digitalis and after subsequent relapse, the patient dies with a clinical or post-mortem diagnosis of heart failure. The original rheumatic causative factor, the dampness responsible at the onset, the subsequent acute 'growing' limb pains and joint trouble and the carditis have too often been completely overlooked or forgotten, alike by patient and doctor, or, if recalled at all, they are probably entirely unconnected with the subsequent heart failure. Frequently perhaps the early rheumatic symptoms have been so slight as to have entirely escaped notice, i.e., they have been subacute in nature, or rheumatic symptoms may have been entirely absent, as is indeed by no means unusual. Small wonder then that rheumatic infection in India has so often been considered 'non-existent' or 'very rare'.

The illustration of the clinical stages and of the correlated pathological processes of rheumatic infection in the King George's Medical College Museum of Pathology

Pathology

In the King George's Medical College Museum of Pathology each of the above-named stages is illustrated by exhibits which display the pathological processes, correlated with the clinical symptoms and signs on typed charts, by framed photographs or by clay models, made in the department, or by actual meat specimens. The arrangement is set out below and is further

illustrated in the accompanying photographs, from which some exhibits are missing:—

Stage I. Acute or subacute tonsillitis

Exhibits:—

1. *Typed chart*

Pathological process—

Acute hæmolytic streptococcus infection.

Clinical process—

History of repeated exposure to damp, or of chill, or of recurrent tonsillitis.

2. *Model, showing chronic tonsillitis.*

3. *Model, showing damp environment.*

4. *Stained throat smear.*

Long-chained streptococci, with pus cells.

Stage II. Quiescent

Exhibits:—

1. *Typed chart*

No clinical symptoms. Perhaps chronic tonsillitis, and some anæmia.

Stage III. Acute or subacute endocarditis

Exhibits:—

1. *Typed chart*

Pathological process—

Acute or subacute mitral valvulitis. Myocarditis. Pericarditis.

Symptoms—

Fever, dyspnœa, point pains, cardiac pain.

Signs—

Cardiac dilatation. Soft systolic murmur.

2. *Clay model*

Vegetations on mitral valve.

Stage IV. Symptomless

Exhibits:—

1. *Typed chart*

Pathological process—

Contracting mitral fibrosis; Enlarging L. auricle; Smaller L. ventricle.

Signs—

'Slapping' first sound; Presystolic murmur, after exercise.

Stage V. Effort syndrome

Exhibits:—

1. *Typed chart*

Pathological process—

Sclerosis; and atheroma; pulmonary artery; back pressure in lung; congested capillaries, bronchial catarrh, blood oozing infarction, brown induration, hydrothorax.

Symptoms—

Dyspnœa; Cough; Brown sputum; Hæmoptysis; Precordial distension; Pain.

Signs—

Presystolic murmur; Pulmonary first sound increased; 'P' wave +; R. V. preponderance.

2. *Model.*

Pulmonary artery showing sclerosis and atheroma.

3. *Coloured lung section, showing:—*

Chronic passive congestion, with muscle hypertrophy (fibrous), induration and pigmented heart-failure cells in alveoli.

4. *Electrocardiogram, showing:—*

Accentuated 'P' wave, and R. V. preponderance.

5. *Model of European girl's face.*

High coloured cheeks and lips; Often blue eyes, fair hair.

Stage VI. Auricular fibrillation

Exhibits:—

1. *Typed chart*

Pathological process—

Auricular failure.

Symptoms—

Continuous dyspnœa; Orthopnœa; Palpitation.

Signs—

Auricular fibrillation; No presystolic murmur; Mid-diastolic murmur; Rheumatic nodules.

2. *Photo:—Of orthopnœic ward patient.*

3. *Electrocardiogram.*

Typical irregular irregularity.

Stage VII. Tricuspid regurgitation. Cardiac water-logging

Exhibits:—

1. *Typed chart*

Pathological process—

Whole heart dilates; Mitral and tricuspid regurgitation; Venous back pressure.

Symptoms—

Congestive failure; Cardiac œdema.

Signs—

Pulse, rapid and feeble; Apex beat, diffuse and feeble; Systolic murmur.

2. *Model.*

Enlarged square-shaped heart.

Stage VIII. Post-mortem diagnosis

Congestive heart failure; Rheumatic mitral stenosis.

External appearance

A young adult, often 20 to 25, ascites, general anasarca.

Internal appearance

Cardio-vascular system

Of heart, L. A., R. V., and R. A., only seen, because enlarged.

L. A., especially, hypertrophied and dilated. Endocardium, opaque.

Anti-mortem appendix-clot.

Mitral valve, cusps thickened, opaque, edges adherent.

Button-hole, diaphragmatic or funnel-shaped.

Chordæ and papillary muscles, shortened.

Pulmonary artery, atheroma.

Respiratory system

Bronehi, brown-tinged mucus.

Lungs bulky (blood), firm (fibrosis), and dark (haemoglobin). (Brown induration). Infarcts, triangular, raised, red solid.

Digestive system

Mucous membrane congested. Contents, blood stained.

Liver, congested, enlarged, nutmeg.

Spleen, congested, deep purple, tense, rounded, firm.

Infarcts, white, firm, triangular or reetangular, early hyperaemic outline.

Kidneys, congested. Capsule, tense. Pyramids, dark.

Cortex, red streaks (vessels), red dots (glomeruli) and grey streaks (tubules).

Infarcts, white, triangular.

Brain. Cream cysts from old infarcts.

A typical clinical life history of rheumatic infection as might be read at a post mortem

The child was taken ill with fever and heart pain after being rain-soaked in the monsoon and sleeping through a night on the wet ground. The large joints were then acutely inflamed and exquisitely tender. Gradual recovery. A relapse of joint pains with pericarditis and a pleural rub for three weeks after a severe drenching in storm rain. No further symptoms for five years when dyspnoea and cough with brownish sputum (heart-failure cells) gradually developed. The voice became husky from pressure of the enlarged left auricle on the recurrent laryngeal nerve. One haemoptysis and persistent precordial discomfort followed. Auricular fibrillation was controlled for some time with digitalis. Towards the end a severe splenic pain for twenty-four hours and transient slight hemiplegia for three days were probably due to embolism. Slow death with increasing water-logging.

Conclusion

If diseases in general were grouped in the museum of pathology in some such manner as this, viz, to illustrate the *progressive* stages through which each disease passes and with each such stage the clinical symptoms, signs and findings were briefly described, then each disease process would become far more readily intelligible to the student, and more readily demonstrable by the teacher. And the knowledge of each individual disease would be clarified and enriched. And if the disease selected for the demonstration of this principle were rheumatic fever, then the knowledge of the occurrence, prevalence, cause, early recognition and importance of rheumatic infection in Indian children and young Indian adults, the existence of which in India is still by many definitely doubted or only regarded as being of great 'rarity', would be increasingly recognized.

PRESENT POSITION OF THE OPIUM SMOKING HABIT IN INDIA

PART II. PREPARATIONS OF OPIUM USED FOR SMOKING AND MODE OF INDULGENCE

By R. N. CHOPRA, C.I.E., M.A., M.D., Sc.D. (Cantab.)
M.R.C.P. (Lond.)

BREVET-COLONEL, I.M.S.

Honorary Physician to the King

and

G. S. CHOPRA, M.B., B.S.

(Department of Pharmacology, School of Tropical Medicine, Calcutta)

In a previous paper we have given an account of the incidence of the opium smoking habit in India. We carried out a general survey of the occurrence of this habit in different provinces and by extensive work in the field collected statistics with regard to the approximate number of addicts in each province. In this paper we propose to deal with the preparations used for smoking, the methods of smoking, the types of persons addicted to this habit, and the control exercised by the state in suppressing this habit.

Preparations used for smoking

The excise opium as it is sold in this country in licensed shops is not suitable for smoking. It is, therefore, necessary to convert it by certain manipulations into a suitable preparation. This process requires certain equipment and takes a good deal of time, and this fact is probably responsible for the existence of opium smoking dens, as it is here that opium for smoking is prepared and sold.

In India two preparations of opium are generally used for smoking. These are *madak* and *chandu*. A third preparation which is rarely used in this country is opium *dross*.

(Continued from previous column)

Summary

1. Disease is best regarded as a continuous process usually progressing through well-recognized clinical stages.

2. With each clinical stage, the clinical symptoms, signs, instrumental investigations, laboratory and radiological tests and post-mortem appearance can be correlated.

3. In a 'living' museum of pathology, one division should deal with the pathological processes in individual diseases and illustrating each disease grouped in such stages and correlated with clinical signs and symptoms.

4. An outline of such a division in the King George's Medical College Museum of Pathology is given.

5. The eight clinical stages through which rheumatic infection often progresses are enumerated, and the exhibits illustrating each stage in the museum of pathology are described and photographed.

Madak.—The use of *madak* in India is much more extensive than of *chandu*, and in most parts of the country this preparation is smoked. The following is, briefly, the method employed for its preparation:—

Raw or excise opium is mixed with water which is then heated to boiling point. The boiling is continued and the impurities which form as a scum on the surface of the boiling fluid are gradually removed. The heating is continued till a thick suspension is formed. This is then strained through a piece of cloth and charred leaves of *Acacia arabica* (*babul*) are gradually mixed with it till it assumes the consistency of a thick stiff paste. This mass is then rolled into small balls called *madak golis* which are available for smoking purposes. As a rule $2\frac{1}{2}$ ounces of *madak* are prepared from one ounce of opium. Sometimes instead of *babul* leaves, leaves of *Phyllanthus emblica* (*amla*), *Acacia leucophlœa* Wild (*safed babul*) and *Piper betle* Linn. (*pan*) are used. In former days, burnt gold or silver threads (*kalabatoo*) were sometimes added to the mass as it was supposed that these imparted to the mixture aphrodisiac and tonic properties. We have, however, not been able to trace this practice in India at the present time.

In Assam, a slightly different method of preparation is employed and to this preparation the name *kanipankhawa* is given. The required quantity of opium is put on a ladle or a spoon, called a *heta*, along with some water, and this is heated for twenty to thirty minutes till it becomes thick in consistency. The impurities are removed as heating goes on by means of cotton-wool. After pouring out the decoction from the *heta* into a small pan, it is cleaned and washed and again heated for about half an hour till it is converted into a sticky paste; this is put aside. Betel leaves are cut into fine pieces and fried in an iron pan called *keraki*. The sticky mass of opium and the fried betel leaves are mixed together and heated until the leaves assume a greenish-brown tinge. The mixture is then ready for smoking.

Chandu and chandul or clarified opium.—This is a stronger preparation and is only used in India by persons who are heavy smokers, or by the Chinese smokers. *Chandu* is prepared by boiling a strained solution of opium in water in a large copper cauldron till it becomes thick in consistency. As the concentration proceeds crusts form on the surface of the simmering mass. These are removed as they form, until finally a thick mass of the consistency and appearance of coal tar is obtained. This is the 'smokable extract' and is the *chandu* or *chandul* of opium smokers. The *chandu* commonly smoked is often adulterated by addition of *dross* scraped from *chandu* pipes which has a high morphine content.

A perusal of the literature shows that in former days *chandu* was used in certain parts of India though perhaps to a limited extent.

This is shown by the fact that the word *chandubaz* or *chandu* smoker frequently occurs in the old records. At the present time, smoking of *chandu* is practically confined to the Chinese population in this country, though the method is not entirely unknown to Indian smokers. In the Far East *chandu* is the chief preparation employed by smokers.

Opium dross.—Opium *dross* is the residue left in the pipe when either *chandu* or *madak* is smoked. The quantity of the *dross* produced depends on the type of the pipe used and the method of smoking employed. Usually the amount of *dross* produced corresponds to a maximum of 60 per cent and a minimum of 40 per cent of the quantity of the prepared opium smoked. The amount of *dross* produced by *madak* smoking is much less in quantity and varies from 20 to 30 per cent of the amount smoked. As *dross* is sometimes used for smoking purposes, the question of its morphine content is important. Very little work, however, is done in this connection, but W. E. Dixon has shown that only a small percentage of the morphine content of prepared opium is absorbed by the smoker when inhaling the smoke. Most of the alkaloid must either be destroyed or left behind in the *dross*. Chemical analysis of *dross* showed that the actual amount of morphine in this substance is not more than the amount contained in the prepared opium from which it is obtained. As the *dross* amounts to only about 50 per cent of the weight of the prepared opium smoked, it would appear that a proportion of morphine is destroyed during the process of combustion of opium.

The question of morphine content of prepared opium and *dross* and the harm resulting from the use of *dross* needs further investigation. So far as India is concerned, however, it is of minor importance. It has been observed that the old and inveterate smoker sometimes mixes *dross* with prepared opium in order to enhance its intoxicating effects. Others and especially those with small means make pills of *dross* and take it by the mouth when they cannot afford to buy prepared opium to indulge in a smoke. They are also known to put *dross* into tea, coffee or other beverages.

The *dross* is usually prepared for smoking by mixing it with water and subjecting it to heat till it assumes a thick consistency. This prepared *dross* is smoked in the same way as prepared opium and leaves a residue in the pipe which is called *second dross* (in the Netherlands Indies *dit-jingko*). The *second dross* is often consumed in very much the same way as the original opium *dross*. It is generally believed that the smoking or ingestion of *dross* is more harmful than the smoking of prepared opium. The reason for it is not known but it is possible that the high alkaloidal content of this substance is responsible for this belief. Failure, partial or complete, to collect the *dross* produced from licit opium thus becomes a serious defect of any

opium control system and the gravity of the situation is further increased when the *dross* resulting from the smoking of illicit opium is taken into consideration. As a measure in combating the illicit traffic in *dross* the excise authorities in some places have introduced a system of purchasing *dross* produced by smoking.

madak goli is smoked in an ordinary *chillum* or a *hookah*, made of two pieces of hollow bamboo one thick and the other thin. One end of the thin piece is fitted into the thicker piece in the form of a letter V, the free end acting as a mouth piece. Besides the pipe, the smoker requires a brazier, a pair of tongs with a sliding

Fig. I.—Showing different kinds of apparatus used for smoking opium in this country.

1. Pair of tongs. 2. A steel stylet or *seekh*. 3. Gouge for removing burnt opium from the bowl of the pipe. 4, 5 and 6 are opium smoking pipes. 7. A *hookah* used for smoking *madak*.

Modes of indulgence.—Different kinds of apparatus have been improvised in various parts of the country for smoking opium. The one commonly used consists of an elongated wooden pipe (made from bamboo or desert acacia), twelve to eighteen inches in length and three-quarters of an inch in diameter. One end fits into a small china or earthenware bowl, and the other end is the mouth piece (figure I, nos. 4 and 5). Sometimes both ends are decorated with thin copper, silver or brass plates or wire. In Assam and in some other parts of the country

clamp and a steel stylet (*seekh*) for clearing the hole in the pipe in case it gets blocked (figure I, nos. 1, 2 and 3).

The method of smoking *madak* is simple. The bowl is slightly warmed and the *madak goli* is placed in the bowl. A glowing charcoal is applied and simultaneously several pulls are made through the mouth piece inhaling the smoke deeply into the lungs.

When *chandu* or clarified opium is smoked, the technique is somewhat different. The bowl is at first warmed by holding the pipe over the

brazier so that the mass of opium placed in it becomes sticky and begins to melt. The temperature to which the bowl is heated is of importance, because, if it is too high, there is danger of the opium melting rapidly, becoming charred, and emitting a disagreeable odour. After the bowl is properly warmed, a small piece of *chandu* or clarified opium is placed on one side of the hole leading into the pipe or just over it. In the latter case a hole is made through the opium mass with the stylet. The bowl is again warmed and, as the opium softens, it is stirred with the stylet until it forms a thick

According to some this is done in order to get rid of the bitter taste of the opium smoke, while others consider that the object is to get the smoke into the stomach to get enhanced effects. Hot tea is generally provided during winter and spring time, but a syrup of lemon and sugar *sekkanjebeen* during summer season.

The method followed by the Chinese and some of the old Indian addicts in Bombay and Calcutta for smoking *chandu* and sometimes for opium dross is somewhat different. The apparatus required consists of an opium pipe, a stylet, a lamp and a head rest.

Fig. II.—*Madak* smoking in a *madak* den.

Fig. III.—Apparatus used for smoking *chandu* and an addict smoking this drug.

coffee-coloured mass. A piece of glowing charecoal is then held with the forceps close to the opium and the smoker applies his lips to the other end of the pipe. When the opium is on the point of melting, he actually places the burning coal on it, and gives a few rapid and deep pulls inhaling the smoke into the lungs. The actual process of smoking lasts less than a minute, and then more opium has to be taken if it is desired to continue smoking. The smokers inhale the smoke deeply and after each pull at the pipe sweet articles, such as plantains, sugar-cane, or tea with sugar are often taken.

The dose of *chandu* (prepared opium) is heated at the end of the stylet over a flame, the stylet end being alternately dipped into the opium and exposed to the flame until a little ball of roasted opium is formed on the point of the needle. The needle is then pushed into the pipe head through the little ball of opium thus formed. The pipe is now ready for smoking. The opium mass is held over the flame while the smoker inhales deeply a number of times getting smoke well into his lungs. The actual smoking of this pipe also takes about a minute and the whole process of preparation must be

repeated for the next pipe. The old smokers generally smoke six to eight pipes at a time after which they fall into what appears to be a peaceful slumber.

Types of addict

Three classes of opium smokers may be described:—

(i) *Occasional smokers*.—This class is ordinarily addicted to opium eating, but indulge in a smoke (of a pull or two of *madak* or have a few whiffs at a *chandu* pipe) occasionally when an opportunity offers itself, such for example as when they are in the company of opium smokers. These persons are as a matter of fact aware of the evil consequences of over-indulgence and have enough strength of mind to limit the amount of smoking. Properly

two-thirds of our cases. The dose in this case ranged from 40 to 180 grains a day. An enquiry made in the areas where the habit is still prevalent showed that most of these addicts belong to lower and mendicant classes who have very meagre means; a few belonging to better classes are generally individuals who have tried all narcotic drugs, such as ganja, charas, opium, alcohol and cocaine, etc. Not infrequently the excessive smokers are morally degenerate and, when they have no money for their usual smoke, beg and commit thefts. Eighty per cent of the excessive smokers in our series were Mohammedans and 20 per cent were Hindus. Hackney-carriage drivers, mendicants and some prostitutes are amongst those who consume large doses and repeatedly indulge in the smoke several times in a day.

Fig. IV.—Interior of an opium smoking den in Nagpur town.

speaking these individuals are not active smokers, but may be potential ones who may take up the habit any time when they have sufficient means as their will-power is weakened.

(ii) *Regular but moderate smokers*.—The majority of the addicts in this group are from the artisan class, such as hackney-carriage drivers, domestic servants, labourers working in tea garden and forest areas, etc. These persons smoke once or twice a day and are in the habit of consuming up to 20 grains a day. Many of them earn from eight annas to one rupee per day and spend a large amount of their earnings on their dope. They generally smoke in the evening after the day's hard labour is over and it is mostly done in their homes, but may also be indulged in a regular opium den on a holiday. Such addicts are now decreasing in number and in the present series formed about one-third of the total number.

(iii) *Regular and excessive consumers*.—This class is very much more numerous than the preceding two classes and comprised more than

Smoking establishments and social nature of the habit

Unlike opium eaters, who generally seek solitude in order to indulge in their cravings, the opium smokers prefer to smoke in company of other addicts. For this purpose they assemble at specified hours and in specified places, in the morning, afternoon or evening. It is for this reason that smoking of opium is preferred in organized establishments rather than in private houses. The majority of the smokers do not possess a pipe or other accompaniments required for smoking opium. A satisfactory pipe costs a few rupees and a good pipe much more. On account of these difficulties, smoking dens where all facilities are provided have existed ever since the habit of smoking originated. Smoking establishments are also encouraged by the fact that smokers have no suitable places of their own where they can retire for a smoke. Most of the smokers are afraid to smoke at home as other members of the family are likely to object to it. For the homeless individuals or those

living far from their homes, a smoking den may be the only place for a night's rest.

The opium smoking establishments in this country are generally dirty, dingy and ill-ventilated rooms located very often in the remote and unfrequented parts of the town. There is little else in these except a few old worn-out mats on which the smokers sit or lie down. There they can smoke the drug unmolested and unknown to their relatives and friends, who might stand in the way of their indulgence. As the place gets known to the addicts it attracts more and more smokers. There are a number of dens in large towns like Bombay even at the present time, though they are often difficult to trace. Generally there is a man in charge who either lives on the premises or at least spends most of his time there. As a rule he is an indigent person who has been an addict for the greater part of his life. He may be a Hindu or Mohammedan according to his clientele and when the latter he is generally addressed as *ustadji* or master. He is generally an old emaciated, pale and anæmic looking individual. He sits on a dirty piece of matting with smoking pipes and some prepared opium which he sells to his clients at a small profit. He may supply ready-made *madak* or *chandu* to the addicts on payment or may merely supply the opium pipe and the necessary equipment. Poor class addicts as a rule buy their dose every time they smoke, but those who can afford it buy the maximum quantity of opium allowed under excise regulations and manufacture their own *madak* or *chandu* as the case may be, portions of which they smoke at leisure. Little or no care is taken to clean, much less to disinfect, the pipes after they are used by smokers and in this way the pipe often serves as a source of spreading contagious diseases, such as syphilis and tuberculosis.

In spite of the restrictions placed by law, opium smokers prefer to smoke in company. The smoker feels happy while he is watching others and is watched by others. All sit on the floor or on a platform. The social distinctions disappear and the smokers take part in the ritual of preparation in the most leisurely fashion and with much good humour. Tea and sweets are brought in and served to all those present. The glowing of the brazier and the manipulation of the pipe are kept up with the utmost relish and enjoyment. All combine to make the sitting as pleasant as possible; there is no hurry and no thought of anything else. This is the sort of 'atmosphere' the smokers like to secure, even though they may be in the dark corner of some smoke-blackened opium den. In places where the restrictions are severe and assembly is not allowed, the smokers frequently meet in the house of one or other of their members and smoke together. There is little doubt that these parties are looked upon with disfavour, because at such meetings young men commonly acquire

the habit; and also parties of smokers are not infrequently suspected of being responsible for petty thefts in the village in order to obtain money for buying the drug for a smoke.

Semi-religious and social aspects of the habit

Smoking of opium used to be a common practice in old days at such social gatherings as marriages and funerals in certain parts of Assam. The custom required that opium should be distributed among the smokers who were present on such occasion. Of recent years also a ceremony purporting to be of a semi-religious nature, the *kenia seba* (the serving of opium), has been found to exist among the more ignorant classes in Assam, at which opium addicts assemble and opium is distributed with the object of averting sickness or other troubles sent by Providence. The distribution and consumption of opium was also common at *namgoa* (the name-giving ceremony). These semi-religious uses of the drug are purely the inventions of interested opium consumers and have no authority from the Sastras (religious books). They are looked upon with disapproval by the better classes and are rapidly disappearing.

Madak smoking is stated to have existed formerly on a much more extensive scale when opium was not only more easily available but was much cheaper in price. Certain families are said to have been ruined by the habit. The number of smokers is declining as opium is getting dearer and restrictions against smoking are increased. Opium eating is now found to be cheaper and less troublesome and many smokers are taking to opium eating instead. The average expenditure of a *madak* smoker is about Re. 0-4-0 per day or roughly 180 grains a week and of *chandu* smoking is considerably more, as compared with one or two annas per day of an average Indian opium eater. Owing to restrictions placed during recent years on smoking opium, the opium dens in this country are rapidly disappearing.

Control of the opium smoking habit by Government

It has long been recognized that in India opium smoking stands on a different footing from opium eating. Opium smoking is indulged in almost entirely for its euphoric or pleasure-giving effects, and is a social vice. The danger of its spread, when practised in public, furnishes strong justification for adopting measures which approach as nearly as possible to total prohibition. So far as opium eating is concerned the Royal Commission on opium in 1895 pointed out that as a vice it scarcely exists in many parts of India. This, however, is not true. The Commission found that opium was extensively used for non-medical and quasi-medical purposes, and that it would not be practicable to draw a distinction between them in the distribution and sale of the drug. The Commission considered that it was not necessary that

the growth of the poppy and the manufacture and sale of opium in British India should be prohibited for all except medical purposes. The Opium Commission also found that the drug was taken in moderation by the average Indian for its mild stimulant effects, as a prophylactic against malaria, for the relief of pain and in the treatment of disease. It was in fact a household remedy for many ills, and it was said that in small quantities eating of opium was less injurious than the consumption of alcohol in many countries in the west. Centuries of inherited experience had taught the people of India discretion in the use of the drug, and its misuse was a negligible feature in Indian life. The above conclusions were also accepted by the Shanghai Commission, who, while they recommended suppression of the practice of opium smoking, refrained from advising the abandonment of the policy of the regulation by which the practice of smoking in this country has hitherto been successfully kept under restraint. The present authors in a previous communication have shown that the habit of opium eating in very small quantities as it exists in some parts of India can scarcely be called addiction or vice and that it does not produce harm.

In 1860, i.e., 34 years after the annexation of Assam, the cultivation of the poppy was entirely suppressed, opium was issued from the treasury alone, and the price was raised in order to prevent its excessive use. Further, in 1925, under the agreement arising out of deliberations of the First Geneva Opium Conference of the League of Nations, India is bound to take measures to reduce the consumption of prepared opium so that it may be completely suppressed within 15 years. Prepared opium is defined as any product of opium obtained by a series of operations designed to transform it into an extract for smoking purposes. Even before this conference, according to the Hague Convention of 1912, all provinces of India were under an obligation to suppress opium smoking. In Assam and other provinces an Opium Smoking Act is in force, which prohibits smoking of this drug.

Under the existing law smoking is subject to very severe restrictions. The sale of the preparations of opium for smoking purposes is absolutely prohibited throughout India, while their private manufacture is only allowed to the smoker himself, or, on his behalf, from opium lawfully in his possession, and to the extent of 180 grains (one tola) at a time. The quantity of opium daily used by an opium eater and the inconvenience and difficulty involved in the repeated preparation for the smoking are so great that these restrictions practically amount to total legal prohibition.

Although this policy of reduction in consumption by raising the price has been followed for the past 60 years, it was found necessary in Assam in 1919-20 to adopt more stringent

(Continued at foot of next column)

INCIDENCE OF BRONCHIECTASIS IN ASTHMA

By R. VISWANATHAN, B.A., M.D., M.R.C.P. (Lond.)
Medical College, Vizagapatam

THE investigation was suggested by an accident. A patient who was being treated in the King George Hospital, Vizagapatam, for bronchiectasis suddenly developed a typical attack of asthma. On enquiring into his previous history more minutely it was subsequently found from his relatives that he had suffered from asthma when he was a child of 5. He had this affliction for nearly 3 years. Since then he had apparently been free from respiratory troubles for a period of nearly 25 years. He sought admission to the hospital for the treatment of his present complaint, namely, a cough which he had had for nearly 4 years. This was evidently a case of bronchiectasis superimposed upon, or resulting from, a pre-existent asthmatic condition.

Little mention is made about this subject in the literature concerning bronchiectasis. Ballou, Singer and Graham (1931) who have made a thorough study of the subject do not discuss the relationship between the two conditions, though they give in their aetiological table 2 of their 142 cases as being secondary to asthmatic bronchitis. Hedblom (1931), Kerley (1934), Warner (1935) and others who have also written on the pathogenesis of bronchiectasis do not make any mention of this aspect of the subject.

Fifty consecutive cases of asthma, of duration varying from 3 to 10 years, were therefore investigated to find out the incidence of bronchiectasis in them. Radiographs of the

(Continued on opposite page)

(Continued from previous column)

measures by way of limiting the supply to shops and further in 1927 steps were taken to limit the supply and ration of all addicts below 50 years and to reduce their consumption to nil within 10 years by means of a 10 per cent reduction in their annual ration. The effect of this policy has already been discussed.

lungs after lipiodol injection into the bronchi were taken in all the cases. Fourteen cases showed definite evidence of bronchiectasis. Six showed saccular dilatation, five cylindrical dilatation, and three showed early bronchiectasis with tortuosity of bronchioles and slight cylindrical dilatation.

In ten of the fourteen cases there was clinical evidence of chronic bronchitis with asthma. But in all the cases the history was suggestive of the primary condition being asthma.

Being a believer in the inspiratory theory regarding the pathogenesis of bronchiectasis I suggest that during an asthmatic attack there is a considerable increase in the inspiratory pull on the bronchial walls, particularly on those portions which are weak congenitally or weakened by inflammation. The spasm of the healthy portions of the bronchial wall will only accentuate the irregularity of its contour.

ICHTHYOL AS A TREATMENT FOR GUINEA-WORM

By RAMKRISHNA N. GORE, L.M. & S.

I USED pure ichthyol (Burgoyne, Burbidges) as an antiphlogistic for the resolution of inflammatory conditions with satisfactory results, in place of extract belladonna, the quality of which had deteriorated, during the last war. After a liberal application of ichthyol to the affected part, it is covered with cotton-wool. In a few hours as it begins to dry a contracting effect is produced and the patient feels definite relief.

I therefore tried ichthyol for the resolution of the inflammatory condition in a case of guinea-worm.

The first case treated had severe inflammation of the leg including the knee and a burst papule with an ulcerated surface. The patient was given an ounce of viscid ichthyol to be applied to the whole of the inflamed leg from the knee down to the toes leaving a clear surface an inch round the burst papule, and was told to cover it with cotton-wool. Six doses of a mixture (Alum grs. v, Tr. Lavandulae Co. min. x, Syrup 3ii, Aqua, ad 5i) was given internally three times a day for two days. The next day as the patient felt much relief, the ichthyol application was allowed to remain for a day more. He was told to come the following day after washing the leg by pouring warm water over it, thus dissolving the ichthyol and removing the wet cotton-wool. On the third day the inflammation had greatly subsided and the patient felt much better. The guinea-worm was seen to be protruding from the burst papule and was ligatured. The treatment was repeated and he was told to come again the next day after washing off the ichthyol with warm

water as before. By this time the inflammation had completely subsided and the patient felt completely relieved. The dead worm was slowly pulled out like a string.

The second case had an inflamed ankle. He was given the same treatment with equally good results. In the third case the guinea-worm was in the forearm which was inflamed. The treatment was repeated. With the subsidence of inflammation the patient felt relief, and was quite well on the fifth day. In the second and third cases the guinea-worms could be seen and felt underneath the skin but had made no opening through it.

The habitat of the female guinea-worm is the connective tissue of the limbs and trunk. The tip of the tail comes to a point and is abruptly bent, forming a blunt hook, functioning as a 'holdfast'. In the ordinary course the guinea-worm keeps hold by the hook at the end of the tail till the discharge of ova is complete which takes from two to three weeks. It appears to me that with the drying effect of the ichthyol and the resolution of the inflammatory condition, the guinea-worm is pressed between the skin and the muscular tissues and is forced to give up its hold and probably dies. I cannot say if alum has any effect.

In the three cases I was impressed by the results which were quick and uniform. The treatment is simple and cheap, one to one and a half ounces of ichthyol being sufficient for one application. The advantage is that the patient is cured in a very short time, and thus there is also an indirect automatic check to the spread of infection which otherwise would continue for a number of days. The treatment is therefore both curative and preventive.

I am sending this note in the hope that others may be induced to try this form of treatment and thus test its value more fully.

ADULT HÆMOGLOBIN STANDARDS IN BURMA

By C. F. J. CROPPER

CAPTAIN, I.M.S.

and

B. S. KAHALI, M.B.

Medical College, Rangoon

THE work described in this paper was embarked upon as being within the scope of a department with little leisure for research, and as likely to be a useful beginning in a field so far entirely unexplored.

The category 'Karens' includes Hills and Plains Karens: the category 'Burmans' has no true ethnological justification (the census of 1931 does not recognize a Burman race as such), but for general clinical purposes is convenient.

The subjects under review were selected virtually at random from the city of Rangoon and from villages within 28 miles. The majority were either 'on trials' at the central jail or students at the University and Medical College. The former group represented a wide range, as

none of them had been in residence more than a few days, and thus the standard iron intake of the jail diet had not had time to influence the hæmoglobin figures.

All observations were made between the hours of 10 a.m. and 4-30 p.m. by the same individual. Throughout the Hellige hæmometer was used, calibrated by an oxygen-capacity determination. Every possible precaution was taken to ensure that only healthy subjects were included. Ages ranged from 18 to 45, the majority falling between 18 and 27.

The results are expressed in terms of grammes per cent.

As judged by the 't' test, there is no 'significant' difference between the mean for male Burmans and that for male Karens, but the difference between Burman and Karen females is significant.

The usual difference between males and females in both groups is apparent. The data for each category were analysed for age-group differences, but the variance was not significant.

The significant difference between male Burmans in gaol and male Burman students (table II) suggests that a factor in the hæmoglobin content is the standard of living, but further investigation into the homogeneity of the populations sampled is desirable.

The results show that the means are somewhat below the usually accepted figures for Europeans (15.6 grammes for adult males and 13.7 grammes for adult females).

We desire to express their appreciation of the active co-operation given by the various institutions visited, and their thanks to Mr. E. G. Lewis and Mr. D. B. Lahiri of University College, Rangoon, who carried out the statistical work for us.

SPONTANEOUS INFECTION OF GUINEA-PIGS WITH A SPIRILLUM, PRESUMABLY *SPIRILLUM MINUS* CARTER, 1887

By B. M. DAS GUPTA

(From the Department of Protozoology, Calcutta School of Tropical Medicine)

McCLUSKIE (1930), Robertson (1930), Francis (1936), and Knowles, Das Gupta and Sen (1936) have noted the occurrence of *Spirillum minus* in the naturally-infected mouse, *Mus musculus*. The last-named workers cited an incident in which a wrong diagnosis of rat-bite fever was established on the basis of discovery of spirilla in a white mouse inoculated with the blood of a patient suffering from prolonged fever without any apparent cause. It was later observed that the mouse had belonged to a batch of which more than 50 per cent had natural *Spirillum minus* infection. They also showed that inoculation of blood of the naturally-infected mouse into human beings could produce rat-bite fever in these hosts. As young guinea-pigs are also susceptible to *S. minus* infection, these workers examined the blood of 20 guinea-pigs for natural infection with the spirillum. This having proved negative they suggested that young guinea-pigs might be used for diagnostic inoculation in the case of suspected rat-bite fever.

Recently, in the course of my experimental studies on leptospiral infections in guinea-pigs, it has been observed that, out of 42 guinea-pigs examined so far, four harboured natural infection with a spirillum; there were organisms present in fairly large number in the guinea-pigs' peritoneal fluid, although they could not be demonstrated in the blood of each of these four on careful search. The preponderance of spirilla

TABLE I

Class	Sex	Size of sample	Mean	Standard deviation	Range (Mean \pm 3 S.D.)
Burmese	Male	100	14.38	± 1.46	10.00 — 18.76
	Female	84	12.23	± 1.36	8.15 — 16.31
Karen	Male	65	14.69	± 1.59	9.92 — 19.46
	Female	37	13.03	± 1.125	9.65 — 16.41

TABLE II
Burmese males

	Size of sample	Mean	Standard deviation	Range
Students	47	14.89	± 1.42	10.63 — 19.14
'On trials'	46	13.90	± 1.39	9.73 — 18.07

in the peritoneal fluid of mice as compared with the blood has recently been pointed out by the writer (Das Gupta, 1938).

Now that both mice and guinea-pigs are liable to spontaneous infection with spirilla, the only solution that may be suggested is to examine the peritoneal fluid of these animals very carefully on two or more occasions for the presence of natural infection, prior to diagnostic inoculation. Peritoneal fluid can be readily obtained by puncturing the abdominal wall with a fine capillary pipette. The operation involved in this procedure does not in any way upset the animal. The spirillum found in the guinea-pigs

Smear of peritoneal fluid of a guinea-pig experimentally infected with *L. icterohæmorrhagiae* showing natural infection with *Spirillum minus*. (Photomicrograph \times ca. 1050.)

varies very much in length. Forms measuring from two microns to anything up to ten microns or even more have been encountered. Its movement is very sharp, shooting forward and backward in a straight line. It is very difficult to study this organism under the dark ground owing to its extraordinarily rapid motility. The terminal flagella can be demonstrated by examination with dark-ground illumination, with an oil immersion objective and a no. 8 ocular after its movement has slowed down, or by staining with the silver-impregnation method. In morphological character the organism is, therefore, indistinguishable from *Spirillum minus*, the causal organism of rat-bite fever. But whether this spirillum has any pathogenic effects on men has yet to be determined.

THE HYDROGEN-ION CONCENTRATION OF HUMAN FÆCES

By C. L. PASRICHA

MAJOR, I.M.S.

R. K. GOYAL

and

S. LAL

(From the Department of Bacteriology and Pathology, School of Tropical Medicine, Calcutta)

Howe and Hawk (1912) were the first to determine the exact hydrogen-ion concentration of human fæces. They examined samples of fæces from three individuals and found that the reaction of the material examined by them was always alkaline, varying with the different subjects and conditions from pH 7.01 to 8.77. Nelson and Williams (1916) recorded that 29 of the 30 individuals examined by them passed fæces which were acid in reaction and Rettger and Cheplin (1921) reported similar observations. Robinson (1922) found the pH of the human fæces to range between 7.0 and 7.5. The investigations reported in the literature have been scanty, often based on an inadequate number of observations, and the results conflicting. Except for the observations of Knowles, Napier and Das Gupta (1923) who determined the reactions of dysenteric stools no published data are available on the reaction of the fæces of healthy individuals living on different diets and exposed to tropical conditions.

Freshly-passed stools were collected in sterilized dry bed-pans and care was taken to prevent admixture of urine with the specimen. Suspensions of the stool were made in distilled water adjusted to pH 7.0. The suspensions were standardized to a density which allowed a blue pencil mark made on one side of the tube to be just visible when seen through the suspension. Hellige's comparator was used for the estimation of pH values. The examination was completed within 30 minutes of the passing of the stool.

The stools of 214 individuals were examined and the number of stool examinations on which this report is based is 562. The individuals examined were 165 in-patients of the Carmichael Hospital for Tropical Diseases, forty Marwaris who were in-patients of the Marwari Hospital, and 30 new-born babies from the Eden Hospital.

Robertson, A. (1930). *Spirillum minus* Carter, 1887. The Ætiological Agent of Rat-bite Fever. A Review. *Ann. Trop. Med. and Parasit.*, Vol. XXIV, p. 367.

The 214 individuals examined belonged to the following main groups :—

I. Individuals whose dietary was			
Indian	147		
Bengalis on hospital mixed diet including rice	107		
Marwaris (vegetarian diet with no rice)	40		
II. Individuals whose diet was Euro-			
pean	58		
Europeans	29		
Other non-Indians	29		

The thirty new-born babies were breast fed and their faeces were examined during the first fourteen days after birth.

The 165 in-patients of the Carmichael Hospital were individuals suffering from a variety of conditions, but not suffering from any apparent intestinal lesions. They were on ordinary hospital mixed diet. Of the individuals examined 107 were on Indian diet (non-vegetarian and including a liberal supply of rice) and 58 on

a European type of diet. There was no restriction in the dietary and the actual amount consumed was dependent on the appetite of the individual. In a number of individuals the first stools passed after admission to hospital were examined, and, as no appreciable difference was noted in the results of the examination of these samples and subsequent samples, it may be taken that the results represent the actual findings that may be expected in a sample of the general hospital population. The faeces collected from a small series of individuals in apparently good health were examined and similar results obtained.

The forty Marwaris were on strict vegetarian diet consisting mainly of wheaten flour, milk, vegetables and lentils and very little or no rice.

The majority of the individuals were examined repeatedly. In most of the subjects the pH value of the faeces showed but very slight variation from day to day. In a certain number, however, this variation was marked.

The results of the examination of the faeces are given in tabular form.

TABLE I

The reaction of the faeces (calculated on the result of the majority of the samples) in different groups of individuals examined

Diets	Number of individuals examined	PERCENTAGE DISTRIBUTION OF INDIVIDUALS ACCORDING TO THE REACTION OF THEIR FÆCES		
		Acid	Alkaline	Variable
Indian mixed diet (<i>plus</i> rice) ..	107	75	16	9
Indian vegetarian diet (no rice) ..	40	42	58	0
European diet (no rice) ..	58	26	67	7

TABLE II

Showing the result of the examination of the total number of samples examined in the different groups

Diets	Number of samples of faeces examined	PERCENTAGE DISTRIBUTION OF STOOLS ACCORDING TO THEIR REACTIONS		
		Acid (below 7.0)	Alkaline (above 7.0)	Neutral or within the limits 6.9 to 7.1
Indian mixed diet (<i>plus</i> rice) ..	356	74	26	7
Indian vegetarian diet (no rice) ..	51	41	59	14
European diet ..	197	35	65	12
New-born babies, breast fed ..	30	93	7	3.5

TABLE III

Showing the hydrogen-ion concentration of faeces of different groups of individuals

Diets	Number of samples of faeces examined	Percentage of faeces showing different pH values				
		4-5	5-6	6-7	7-8	8-9
Indian mixed diet (<i>plus</i> rice).	356	5	34	36	18	7
Indian vegetarian diet (no rice).	51	0	16	25	35	24
European diet ..	197	3	9	24	48	16
New-born babies, breast fed.	30	10	34	50	3	3

The examination of the fæces was repeated several times in a number of apparently healthy individuals. In the majority the range of variation of the pH values of the fæces was extremely small, or if there was any marked variation it was of a temporary nature. The following eight individuals however showed wide variations in the reaction of samples of stools examined on different days. No adequate explanation can be advanced for such changes.

the ordinary mixed Bengalee diet and the Marwari diet, are not comparable, the one outstanding feature is the presence of rice in fairly large proportions in the former, and very little or no rice in the latter type of diet. In order to determine the effect of rice on the reaction of fæces the rice was cut off in the diet of four individuals and replaced by ordinary bread. The normal diet of these four subjects was ordinary mixed Bengalee diet including rice and

TABLE IV

Showing day to day variation in the pH values of the fæces of eight individuals

Serial no.	1	2	3	4	5	6	7	8	9
1	7.8	6.8	6.8	7.2	6.3	8.5	5.1	5.0	..
2	7.3	7.3	6.5	6.0	8.2
3	7.1	5.7	6.4	7.0	7.5
4	8.1	6.9	7.4	6.7
5	6.4	6.7	8.1	4.8	8.6
6	7.4	5.5	6.1	6.1	7.8	8.0	8.1	7.8	..
7	8.1	7.5	7.8	7.6	7.5	6.9	8.2	8.3	6.8
8	7.9	8.1	7.3	6.9

TABLE V

Showing the reaction of fæces of different consistency. The results are given as percentage of the number of individuals examined

Diets	THE MACROSCOPIC APPEARANCE OF THE STOOL					
	FORMED		SEMI-SOLID		LIQUID	
	Acid	Alkaline	Acid	Alkaline	Acid	Alkaline
Indian mixed diet (plus rice) ..	57	43	75	25	62	38
European diet	—	100	13	87	18	82

It will be seen from the tabulated results that the majority of breast-fed babies examined during the first fourteen days after birth were passing stools which were distinctly acid in reaction. The stools of two babies fed on cow's milk were found to be alkaline. This confirms previous findings.

In European and other non-Indian adults on European type of hospital diet with a comparatively heavy meat intake the reaction of the fæces though somewhat variable tended to be alkaline. The consistency of the stool showed that whereas the formed specimens were invariably alkaline, the majority of the semi-solid or liquid stools were also alkaline in reaction.

The reaction of the fæces of Indians on the two types of Indian diet showed strikingly different results. In the majority of the individuals on hospital mixed diet, which included a liberal supply of rice, the fæcal reaction was definitely on the acid side, whereas in individuals on a strict vegetarian diet with no rice, the fæcal reaction, although in the majority alkaline, tended to be more variable. Although the two diets,

their fæces examined prior to the stoppage of rice were consistently acid in reaction (the average pH was 5.0, 5.3, 5.5 and 6.0). After varying periods (4, 6, 11 and 11 days), the reactions of the fæces became alkaline and remained alkaline as long as rice was excluded from the diet. It appears that the main factor in the determination of fæcal reaction is the diet; a preponderance of carbohydrates produces an acid stool.

Summary

1. The pH of 562 samples of fæces from 214 individuals were determined by the colorimetric method.

2. The fæcal reaction of breast-fed babies was found to be acid whereas those fed on cow's milk were passing alkaline stools.

3. In Europeans and other non-Indian adults on European diet the reaction of the fæces though somewhat variable was alkaline.

4. The reaction of the fæces of Indians varied according to the type of diet. The

(Continued at foot of next page)

HISTORY OF IMMUNIZATION AGAINST TUBERCULOSIS

By L. NÈGRE

Chef de Service l'Institut Pasteur, Paris
and

R. K. GOYAL, D.Sc. (Paris), Ph.D., M.R.C.P. (Lond.)
School of Tropical Medicine, Calcutta

THE isolation and cultivation of the tubercle bacillus by R. Koch gave a great impetus to the efforts to immunize susceptible animals against tuberculosis. The methods of vaccination successfully used in a certain number of bacterial infections were naturally seized upon so as to arrive at the same results in this disease. The discovery of tuberculin by Koch led people to hope that it would be successful in the prevention and cure of tuberculosis. But everyone quickly realized that although it was harmless to tubercle-free animals, it failed to confer the slightest degree of immunity.

F. Klopstock tried to immunize guinea-pigs by injections of gradually increasing doses of tuberculin during several months. On inoculation of the test dose, these animals succumbed in exactly the same way as did the controls. Calmette had the same unsuccessful results in the case of bovines.

I. Strauss thought that a certain degree of immunity could be conferred on rabbits by injecting them every 10 days with very small doses of tubercle bacilli killed by boiling.

Dembinski immunized several rabbits by intravenous injection of increasing doses of killed bacilli (0.00001 gm. to 0.001 gm.). All of these were infected later with 2 mgm. of virulent tubercle bacilli by the intracerebral route. The animals lost weight, but remained alive. Most of them were found to have caseous abscesses in the brain and on the meninges. The resistance conferred was therefore very limited.

(Continued from previous page)

majority of subjects on the hospital type of Bengalee mixed diet which includes rice were found to be passing acid stools whereas in Marwaris on vegetarian diet with no rice the faecal reactions though more variable than in individuals on European diet tended to be alkaline. The exclusion of rice from Bengalee diet and its replacement by bread changed the reaction of the faeces from acid to alkaline.

A durable immunity could not be produced in guinea-pigs by subcutaneous or intraperitoneal administration of dead bacilli. Borrel demonstrated, in rabbits also, that each injection produced either a local abscess or peritoneal inflammation ending in death.

Calmette and Guérin working with bovines did not succeed in producing a durable immunity by intravenous injections of bacilli killed by heat. Use of bacilli heated only up to 65°C. to prevent an alteration of the protoplasm did not give better results. Even when the bacilli killed by age were substituted for those killed by heat the results were not better.

Petroff reported that injections of dead bacilli could confer a certain degree of resistance on guinea-pigs. It appears that only the onset of symptoms was delayed for a few days.

P. Uhlenhuth also failed to immunize animals by administering big doses of bacilli killed by steam or exposure to 150°C. for 30 minutes.

E. Coulaud incorporated the dead bacilli in melted paraffin and injected rabbits or guinea-pigs by the subcutaneous route. He stated that these animals became much more allergic than those receiving only the dead bacilli in saline suspension. The allergy thus produced endured for 2 to 3 years. These animals, tested by an injection of virulent bacilli, presented signs of disease after a much longer period than the controls. But the resistance was transitory and disappeared by the end of a year, the allergy however enduring much longer. A. Sacenz, using vaseline in place of liquid paraffin, came to the same conclusions.

These results lead one to believe that dead bacilli cannot be employed with hopeful results in anti-tuberculous vaccination.

It should be noted that Maragliano since 1903 has utilized bacilli killed by heat in human vaccination. He applies a small amount of concentrated bacillary emulsion in glycerine to a scarified area on the arm. Nathan Raw of Liverpool and Langer in Germany vaccinated children by subcutaneous injection of dead bacilli.

After the experimental failures in the use of bacilli killed by heat the use of organisms treated with chemicals was attempted. Moussu and Goupil used 10 per cent water of Javel, Vallée employed 1/400 dilution of iodine in water, Rappin resorted to fluoride of sodium, Noguchi and later Marxner used oleate of sodium or ammonium, Deycke and Much choline or ovolécithin, L. Rabinowitch formol, and Jousset glycococcol. Other workers have used the diastases, such as the juice of *Drosera* (Loeffler) or certain cellular ferments, protease, lipase, etc. None of these procedures gave satisfactory results.

Bacilli deprived of wax and fats were also experimented with. J. Cantacuzène succeeded in conferring on guinea-pigs an appreciable degree of resistance to the intoxication produced

by defatted bacilli. He gave a preliminary injection of bacillary bodies treated first by methyl alcohol, then by petroleum ether in a Soxhlet apparatus and finally by a special Gram's iodine solution during 15 minutes. Vallée attempted in the same way the vaccination of calves with the bacilli first washed and desiccated and then defatted by petroleum ether in a flask containing glass beads shaken mechanically for 60 hours. He inoculated 25 to 100 mgm. intravenously, the animals thus treated acquired a certain resistance in regard to an intravenous inoculation of a certain dose of virulent bacilli, which produced death in the controls in a short time.

Louis Martin and Vaudremer employed a slightly different technique for defatting bacilli. The bacilli were first soaked in ether to get rid of water and glycerine, then dried and resuspended in ether for 6 weeks. Guinea-pigs inoculated intraperitoneally with this product were occasionally resistant to lethal doses of virulent bacilli, but the results were irregular.

Afterwards G. Dreyer thought that he could not only immunize but even cure tuberculous guinea-pigs by a vaccine called Diaplyte. He treated the bacilli first with formalin then heated them at 100°C. in a water-bath for 24 hours. The bacillary bodies were filtered and extracted with acetone during 24 hours at 65°C. The last treatment was to suppress the acido-resistance and the colorability by Gram's stain. The bacilli were dried and suspended in distilled water: 1 c.cm. containing 0.2 mgm. of defatted bacilli.

Grasset tried to vaccinate guinea-pigs with this product, but got negative results.

None of the methods so far described gave satisfactory results.

Following all these failures, Maffucci was the first in 1889 to vaccinate bovines with human virulent bacilli. MacFadyean in England, and Pearson and Gilliland in the United States also attempted the same procedure.

The really interesting work was started in 1902 by von Behring, Römer and Ruppel. Their method was known as 'bovo-vaccination' or 'jennerization of bovines' of Behring. It consisted in 2 injections into calves of about 6 months of age by the intravenous route at an interval of 3 months, first 4 mgm. then 20 mgm. of a culture of tubercle bacilli of human origin, which were of very reduced virulence to guinea-pigs.

Many experiments of bovo-vaccination were carried out on cattle, from 1902 to 1910 in Germany, Hungary, Denmark, Sweden, Italy and the United States.

In France a vast experiment was undertaken by the Central Experimental Society of Veterinarians to determine the innocuity, efficacy and duration of immunity conferred on cattle by this method. The conclusions arrived at were as follows: The fairly appreciable resistance presented by the vaccinated animals, tested by an

intravenous injection, decreased appreciably after 3 months. The resistance of vaccinated subjects to contagion conveyed by animals with open lesions was little in evidence and disappeared altogether after a few months. The commission also put on record that the bovo-vaccine was of uncertain virulence to guinea-pigs. It could be deduced that the effect on oxen could not be uniform. It was thus well established that the bovo-vaccine of Behring conferred an appreciable resistance on cattle infected naturally or artificially by various routes, but this resistance was of short duration and lasted only a few months. On the other hand, the animals vaccinated in this way eliminated for a long time in their dejecta and especially by their mammary glands, tubercle bacilli with the human character intact. For the individuals taking care of these animals or partaking of their milk, this elimination constituted a grave danger.

In 1905, Robert Koch, Schutz Neufeld and Miessner reported their efforts of immunization of bovines, goats and donkeys with human and bovine bacilli whose virulence was automatically reduced by successive culture in glycerine broth. This vaccine named 'Tauruman' presented the same defects as that of Behring.

After the experiments of the last-named scientist, the most interesting experiments of bovine vaccination were performed by S. Arloing. This author succeeded in culturing human bacilli at 44° to 46°C. in the depth of broth by frequent shaking. The bacilli had thus lost most of their virulence. Inoculated by various routes into small laboratory animals in small doses, the homogeneous bacilli of Arloing rarely produced follicular lesions and were well tolerated by the bovines. S. Arloing used this vaccine in infected rural areas. The tuberculin-negative animals were given two intravenous doses at 3-monthly intervals; no accident was encountered. The test dose of bovine bacilli was given and the animals were sacrificed; after some time 50 per cent showed no lesions on autopsy, 25 per cent had only glands affected and the rest had generalized lesions. The controls injected with the same strain showed the following results:—

Generalized tuberculosis in 67 animals.

Glandular tuberculosis in 27 animals.

Nine animals free from lesions.

In a farm containing 81 per cent tuberculous cattle, 77 per cent of the vaccinated animals did not succumb to the infecting dose. S. Arloing did not determine the duration of immunity conferred by his vaccine, as he died at this stage.

H. Vallée utilized in his vaccination work a bacillus of equine origin which was of slight virulence to rabbits and guinea-pigs. This author stated that the bacillary vaccine suspended in an unabsorbable medium conferred a more marked resistance to tuberculosis than the injection of bacilli as such. He emulsified the

culture of his bacillus in vaseline, mixing it with talc powder or 'grès phosphorisé'. He hoped thus to assure a longer persistence of his vaccine in the animal body.

The Japanese scientists introduced a new method of vaccination with attenuated living bacilli. K. Shiga obtained a strain of tubercle bacilli of low virulence and easy diffusibility by making successive cultures in glycerine broth containing gradually increasing doses of trypanflavine (derived from a chloride of fuchsin) or neutral red; these chemicals had a distinct inhibitory action on the growth of the organisms. The bacilli thus attenuated were of very slight virulence for guinea-pig. Shiga asserted that these bacilli, sensitized by an anti-tuberculous serum, prevented the extension of latent foci in subjects predisposed to the disease and suffering from glandular tuberculosis.

R. Arima, K. Aoyama and J. Ohnawa suppressed the acid-resistance of a human tubercle strain and attenuated its virulence by culturing on media containing a saponin (extract of *Sapindus mukorogi japonica*). This strain produced only very few small pulmonary tubercles in rabbits inoculated intravenously with doses of 10 to 100 mgm. These authors obtained fairly encouraging results in the vaccination experiments conducted on rabbits and guinea-pigs.

Vaudremcr, in his attempts to vaccinate cattle, also employed a strain which had lost its acid-resistance by contact of a Chamberland filtrate of a culture of *Asperigillus fumigatus*.

As we have seen, the work of Behring was responsible for making the world look in another direction in immunological processes; the living bacilli were shown to be much more efficacious than dead. But these ideas did not prove to be of utilitarian value because of the attendant dangers. The same reasons applied to the use of living virulent bacilli, which will be described simply from a historical viewpoint:—

Gerald Webb and W. Williams tried to vaccinate rabbits, guinea-pigs and two infants born of tuberculous parents by injecting repeated small doses of virulent bacilli.

Selter also tried to vaccinate 9 infants with living bacilli. He inoculated them with 10 to 10 thousand virulent bacilli of human type containing the ground-up bacillary bodies. One child died of pneumonia three months after the inoculation but the others remained perfectly well.

Such methods could never be used on a large scale, the subjects thus infected were always in danger of suffering from a generalization of the caseated tubercles; this was shown by Bruyant to be the case in guinea-pigs.

Nègre and Bretey showed that living tubercle bacilli of the S type could be used to confer a marked immunity on guinea-pigs, rabbits and monkeys. But they could not say if these bacilli could become virulent later on, hence their results could not have a utilitarian value.

These experimental observations were in conformity with clinical data.

Marfan showed in 1886 that individuals, who had suffered from glandular tuberculosis in their childhood, rarely suffered from pulmonary tuberculosis later on. The resistance to tuberculosis of adults in big cities was well known. The disease manifested itself in their case in the chronic form and did not advance much. This resistance can be explained by a spontaneous vaccination caused by the ingestion of a few bacilli in their childhood.

Heimbeck and Scheel clearly established that nurses and medical students with a positive tuberculin reaction had very little contact-tuberculosis as compared with those with a negative skin test. Heimbeck observed only two cases of infection in a series of 216 probationers giving a positive cuti-reaction (0.9 per cent). On the other hand, 55 cases occurred amongst 246 negative reactors (22.8 per cent).

It was known that guinea-pigs tuberculized for 3 weeks did not react to a reinfection in the same way as healthy animals. A subcutaneous inoculation of a known virulent strain in the latter caused in about 10 days the appearance of a cutaneous nodule, which ultimately ulcerated and persisted till death. The infection spread to corresponding glands and then generalized.

In the case of the guinea-pigs tuberculized for 3 weeks, a similar inoculation produced at the end of 24 to 48 hours an erythematous patch, which necrosed. The necrosed tissues were eliminated and a scar formed, the infection remaining localized to such an extent that even the corresponding glands escaped.

Allen Krause and Dorothy Peters, Debré and Bonnet have shown that the nodule caused by a reinfection in guinea-pigs previously vaccinated by a strain of low virulence did not progress in the same way as the nodule of a primary infection in a healthy guinea-pig. On intradermal inoculation of a few bacilli in a normal guinea-pig, the nodule did not make its appearance before 8 to 10 days. It ulcerated and the infection generalized. In the vaccinated guinea-pigs, the nodule due to a secondary infection might appear as early as the 4th day. It enlarged up to the 4th week and then retrogressed and disappeared.

On the other hand, Krause and Willis have stated that the subcutaneous injection of a virulent strain in normal guinea-pigs caused a spread to all the organs in 4 days. A similar secondary infection in the case of immunized animals caused the virulent bacilli to remain confined to the regional glands during 15 days. The generalization occurred at the end of 30 days.

Calmette and Guérin observed later on that if a minute quantity of virulent bacilli was administered in food only once to a heifer, it suffered from tuberculosis, reacted to tuberculin during several months, and then recovered. The

animals which had thus recovered could not be reinfected and behaved like vaccinated animals. But if several doses of virulent bacilli were ingested by a heifer, at short intervals, a fatal infection was contracted.

It was thus shown experimentally for the first time that a single contamination of small importance determined a mild infection and passed off, vaccinating the animals. Whilst several repeated contaminations led to a grave illness, which did not pass off and generally ended in death.

Calmette drew attention to the fact that in early life infants born of phthisical mothers were exposed to grave dangers leading generally to death, because not only was the infection massive but was repeated day by day. The statistics prepared by Calmette showed the following rate of mortality in the first year of life of babies born of tuberculous mothers and brought up with them:—

In France—24 per cent.

In Paris—32 per cent.

In Belgium—20 per cent.

From the third year of life of the babies, the contagion was less formidable, because the little ones were less in contact with their mothers and so infection became more intermittent. Calmette concluded from these data that an early but mild infection in men and animals was desirable on condition that it would not be followed by other infections either massive or following closely one after the other. It conferred on the organism a sufficient resistance against the grave and rapidly fatal form of infection.

In view of all these facts, Calmette was led to the conclusion that it would never be possible to vaccinate adolescents or adults in countries either heavily infected or those in which the bacilli were widely disseminated. The introduction of dead bacilli into the system might be risky, causing the supervening of intolerance or activation of pre-existing lesions.

In his view, a method of preventive vaccination could only be useful when applied to the newly born or to individuals totally free from lesions. The idea of utilization of pathogenic bacilli or of those of attenuated virulence was considered dangerous. Calmette and Guérin sought for the living tubercle bacilli, which were avirulent.

In order to obtain easily emulsifiable cultures, Calmette and Guérin cultivated tubercle bacilli on media containing essentially pure ox bile. They found that, in spite of the high alkalinity of the medium, the bacilli developed well on cooked potato medium containing 5 per cent ox bile in glycerine, the aspect of the culture resembling the colonies of glanders. After 13 years of continual subculture representing 230 passages, the extremely virulent bovine bacillus used became incapable of producing inoculable

tubercles in guinea-pigs, even after administration of 1 to 2 centigrammes. In spite of this, it was an excellent antigen and was capable of producing big amounts of antibodies in healthy and tuberculous guinea-pigs. It could be cultivated on the routine laboratory media presenting the normal aspect of tubercle bacilli and produced tuberculin actively.

Sidelights on B. C. G.

The birth of B. C. G. has already been described; we propose to throw some light on its pathogenic and immunizing properties.

Its toxicity as tested by the intracerebral or subcutaneous routes approximates to that of human or bovine tubercle bacilli, but it can be differentiated by its chemical constituents.

Chargaff has shown that B. C. G. is richer than the last two in its total lipoids and in wax soluble in chloroform. On the other hand, the higher alcohols of the wax of B. C. G. are only one-half the molecular weight of those of the corresponding alcohols of the virulent bacilli.

Inoculated by various routes (subcutaneous, intraperitoneal, intravenous, intraocular, sub-arachnoidal or intracranial) up to 1 mgm. into guinea-pigs and rabbits it did not produce any tuberculous lesions whatsoever.

Stronger doses, 5 to 20 mgm., administered subcutaneously into guinea-pigs caused the formation of a cold abscess, which after evacuation healed spontaneously without the tumefaction of neighbouring glands.

One to 5 mgm. injected intracardially into guinea-pigs caused a hypertrophy of the lymphatic system, which disappeared in a short time.

Intraperitoneal injection of doses more than 5 mgm. in amount caused the formation of tuberculous nodules in the omentum which disappeared altogether in a few months.

In the case of rabbits, intravenous injections of big doses (15 to 20 mgm.) caused the appearance in the lungs of small follicles containing giant cells, leucocytes and epithelial cells which regressed gradually and disappeared completely within 6 months of inoculation (Coulaud).

If one inoculated the peritoneal nodules or lung lesions subcutaneously into guinea-pigs, the inoculated animals never developed any tuberculous lesions.

The bovines, young or old, which do not react to tuberculin, support well the subcutaneous inoculation of 50 to 100 mgm. of B. C. G., which is also inoffensive for monkeys especially the anthropoid apes. The same holds good for horses, goats, sheep, pigs, dogs and the animals lower in the scale.

Normal human beings can be given 1 mgm. subcutaneously without causing the satellite lymph-glands to tumefy. These inoculations cause only the formation of a cold abscess at the site of inoculation.

The dose of one centigramme given by mouth and repeated thrice at 48-hour intervals in the case of the newly born, and 10 times the dose in young animals on the breast does not cause any physiological derangement. All these data established by Calmette and his collaborators have been confirmed by numerous scientists (R. Kraus, Gerlach, Prausnitz, Kolle, Kirchner, Aldershoff, Stanley Griffith, Lyle Cummings, O'Brien, William Park, Cantacuzène, Bruno Lange, Tzckhnovitzer, George Blanc and the Ukranian Commission). The members of the Bacteriological Section of the Conference on B. C. G., convened in Paris in October 1928, under the auspices of the League of Nation's Health Committee, have recognized these unanimously as exact, and they have also declared that B. C. G. is an inoffensive vaccine incapable of producing a progressive tuberculosis.

Although B. C. G. is harmless to the animals most susceptible to tuberculosis it is a very good antigen both *in vivo* and *in vitro*.

On the other hand, it sensitizes the animals to tuberculin provided they receive a fairly big dose.

In guinea-pigs the rate of appearance of allergy is directly proportional to the dose administered subcutaneously. Tuberculin sensitization occurs in 15 days after the hypodermic administration of 0.001 to 0.1 mgm. The prolongation of the anteallergic period is noticeable if the dose be less than 0.001 mgm.

One centigramme of B. C. G. administered *per os* 4 to 5 times to guinea-pigs does not sensitize them before 35 to 40 days, sometimes it takes longer.

The allergy persists for 6 to 10 months.

In the rabbit, an intravenous injection of 0.001 to 10 mgm. of B. C. G. induces a sensitization which manifests itself at the end of 8 to 15 days. A dose of 0.0001 mgm. or upwards fails to sensitize occasionally. The allergy persists for 8 to 10 months. Administered *per os* in doses of 5 to 10 centigrammes, it sensitizes not earlier than 5 or 6 months.

The horse reacts to an intravenous inoculation of 10 mgm. by a hyperthermia commencing on the 2nd day and disappearing on the 12th. Each new bacillary injection causes an earlier and shorter febrile reaction, the incubation period being never less than 2 hours.

Numerous experiments have been performed to determine if the B. C. G. regains the virulence in the body of inoculated animals. Calmette and Guérin have shown this idea to be untenable in the case of cattle. They reinoculated the heifer with the cold abscess material produced in this animal by subcutaneous injection of B. C. G.; the inoculated animal remained free from lesions. One can therefore conclude that B. C. G. derived from bovines, having remained in the system of the most susceptible animal for a year and reinoculated into the same species, did not regain its virulence.

Calmette and his collaborators also reinoculated guinea-pigs, under the skin or into the peritoneum, with either the epiploic nodules which result from the intraperitoneal injection of B. C. G. or the lungs of rabbits having undergone an intravenous injection of B. C. G. and containing the small follicular lesions described by Coulaud. The guinea-pigs thus treated did not become tuberculous in any case.

The same experiments were conducted by R. Kraus and Gerlach at Vienna, Bruno Lange at Berlin, Stanley Griffith at Cambridge, William Park at New York, Aldershoff at Utrecht, A. Ascoli at Milan, Kirchner at Hamburg, Tzckhnovitzer and the Ukranian Commission at Kharkoff.

Tzckhnovitzer unsuccessfully tried to make B. C. G. virulent by inoculating it into monkeys and guinea-pigs treated either by (a) small doses of diphtheria toxin, (b) fed on vitamin deficient diet, (c) given gradually increasing doses of tuberculin, or (d) infected by other germs, *e.g.*, streptococci. Successive passages from animal to animal also gave negative results.

Nègre and Valtis did not have better luck in their experiments. The guinea-pigs infected with 10 mgm. of B. C. G. by the subcutaneous route were repeatedly given subcutaneously 1 c.cm. of acetone extract of tubercle bacilli during 2 months, but the B. C. G. remained avirulent.

On the other hand, Petroff claimed to have rendered B. C. G. virulent by successive passages in the testicle of guinea-pigs. He asserted that he dissociated B. C. G. into an avirulent R type and an S type virulent to the guinea-pig. No other worker has succeeded in confirming these observations of Petroff. It is highly probable that the S colony of Petroff came from a virulent bacillus introduced accidentally into his culture. Our contention is strengthened by the fact that B. C. G. is of bovine origin, the S type should have proved virulent for the rabbit, but such was not the case. It must not be forgotten that Petroff himself supplied the R and S colonies of B. C. G. to Neufeld, who concluded that the S type contained a virulent human bacillus and not a bovine one.

Later on Hormaeche, Sassano and Medlar as well as Dreyer announced that B. C. G. could be made virulent by (a) injecting guinea-pigs suffering from a streptococcal infection, (b) by culturing in Sauton's medium containing fresh rabbit serum, and (c) by cultivating in the depth of peptonized and glycerinated veal broth.

These results could not be confirmed by Boquet, Saenz and Sanctis Monaldi.

It is useless to mention the grave accident of Lübeck, where the experts appointed by the German Government concluded that the vaccine prepared locally had been used to immunize infected children and had been contaminated by a virulent bacillus.

Certain clinicians have opined that although B. C. G. may remain inoffensive for years, it may ultimately cause tuberculous lesions. These fears are groundless and no experiments have given cause for such fears.

We know that the bacilli used as vaccine are eliminated gradually and disappear without leaving any trace. At this moment, the immunity which was due to the presence of the bacilli in the system also disappears in its turn.

The autopsies of vaccinated infants have not revealed tuberculous lesions. Zeyland and Madame Zeyland have shown that the organs of such babies contained B. C. G., which was found to be avirulent by animal passage.

To sum up, thousands of vaccinations conducted for the last 7 years have established that the general mortality is relatively lower in the vaccinated than the non-vaccinated. It proves that the hypothesis of the regaining of virulence by B. C. G. after a time is without foundation.

Certain authors have wanted to link immunity to hypersensitivity. Immunity cannot exist unless the tuberculin tests are positive. In Koch's phenomenon, the tuberculous guinea-pigs are at the same time hypersensitive and refractory to infection. Koch was of opinion that reinfection did not occur because the bacilli used in the test were destroyed in the necrosed tissues and later eliminated.

Afterwards Calmette, Römer, Bezancon, Serbonnes, Rist and Rolland, Debré and Bonnet, Boquet and Nègre have tried to differentiate immunity and hypersensitiveness in the phenomenon of Koch.

An intradermal inoculation of a small dose of Koch's bacilli into a tuberculous guinea-pig does not produce Koch's phenomenon, but no reinfection actually occurs. Only the immunity intervenes without any manifestation of hypersensitivity (Römer).

But a moderate dose of bacilli injected intradermally into tuberculous guinea-pigs provokes the phenomenon of Koch without any reinfection. Immunity and hypersensitivity manifest themselves simultaneously. It should be borne in mind that the immunity conferred by the bacillary vaccine establishes itself progressively, its slowness presents a great contrast to the rapidity of sensitization.

The guinea-pigs which received 50 to 100 mgm. of B. C. G. subcutaneously reacted to tuberculin on the 5th day, Koch's phenomenon could be elicited at the end of 8 to 20 days and immunity appeared as much as 30 days later.

The bovines vaccinated by an intravenous injection of 50 mgm. of B. C. G. reacted irregularly to tuberculin, were immunized at the end of 6 weeks and ceased to react at the end of 4 to 6 months, but the immunity persisted at least a year.

Dead tubercle bacilli and paratubercle bacilli do not immunize the injected animals but sensitize them to tuberculin.

Immunity and hypersensitivity are therefore two distinct and independent states of the organism infected with Koch's bacillus.

Sensitization to low dilutions of tuberculin proves that B. C. G. is absorbed and retained by the organism. This indicates that the conditions necessary for immunization with B. C. G. are actually produced.

The experiments (detailed below) on small laboratory animals, cattle and anthropoid apes have shown that the B. C. G. introduced by the subcutaneous, intravenous or digestive routes, confers a state of resistance. The resistance varies according to the susceptibility to tuberculosis of the various animal species.

By an intravenous injection into a rabbit of 15 to 20 mgm. of B. C. G., one can protect this animal against tuberculous infection, fatal in 50 to 75 days in the controls. But the resistance thus conferred decreases from the 6th month onwards. The test bacilli remain in the system and produce benign and well-supported lesions. Generalization and death sooner or later are rarely encountered.

Young rabbits, 15 to 20 days old, can be vaccinated by the oral route by administering with a pipette 20 mgm. of B. C. G. 5 to 10 times at 24-hour intervals. Tested 3 months later with a dose of 1 mgm. of virulent bovine bacilli, given in 1 to 2 meals, they survive much longer than the controls of the same age, and present only discrete lesions whilst the non-immunized die of visceral tuberculosis.

Rabbits vaccinated by the intravenous or subcutaneous route react to tuberculin from the 15th day onward and continue to give positive reactions up to the 8th month.

It is possible to confer the same resistance on guinea-pigs by (a) an intracardiac injection of 5 to 10 mgm., (b) by giving two subcutaneous injections of 50 mgm., or (c) by ingestion of 100 mgm. in 10 meals. But it is stated that, as in the case of rabbits, the immunity starts to disappear from the 6th month after vaccination. The adult guinea-pigs, vaccinated by the subcutaneous route, reacted to tuberculin from the 5th day onward, and those immunized by the oral route reacted from the 32nd to the 47th day.

Similar results were obtained in guinea-pigs and rabbits by Imamura and Takahashi, Lange and Lydtin, Okell and Parish, Rancovitz, Rolle, Satake, Tzekhnovitzer and Kochkine.

Calmette, Boquet and Nègre have shown that subcutaneous injection of 2 mgm. of B. C. G., repeated 10 times on alternate days, confers a better immunity on guinea-pigs than a single dose of 20 to 30 mgm. of the bacillary vaccine. Lately J. Beerens has shown that the repeated subcutaneous injections into guinea-pigs (20 to 30 times on alternate days of 0.01 mgm. of B. C. G.) confer a degree of resistance,

ANTI-MALARIAL MEASURES IN THE RAILWAY AREA AT DELHI

By B. L. CHOPRA, L.R.C.P., M.R.C.S., L.M., D.P.H., D.T.M.
Divisional Medical Officer, North Western Railway,
Karachi

AN intensive anti-malarial drive was undertaken by the Government of India to rid the Imperial Headquarters of malaria during the summer of 1936 (under the supervision of Lieutenant-Colonel Covell, I.M.S., Director of the Malaria Survey of India).

(Continued from previous page)

which cannot be equalled by a single administration of 0.2 to 0.3 mgm. These observations have been confirmed by Ch. Duprez.

L. Nègre has also demonstrated in the case of guinea-pigs that a known quantity of bacilli administered in divided doses, e.g., 5 centigrammes given in 5 doses of 1 centigramme on alternate days, is more efficacious than a single big dose. The percentage of positive tuberculin reactions rises and the resistance to the test dose is more marked. This observation is of great value from the point of view of vaccination.

Working with pigs and goats, Ascoli has demonstrated that vaccination by the subcutaneous route was superior to that by the oral route.

Experiments on cattle have shown that these animals having been given 20 to 30 mgm. of B. C. G. intravenously or 100 mgm. subcutaneously can be safely injected with 3 mgm. of virulent bacilli. The controls injected at the same time die in 3 to 4 weeks with generalized lesions in all the organs.

Wilbert has put in evidence the resistance of chimpanzees and cercopithecus to a virulent infection, these animals having been treated with 50 mgm. of B. C. G. by the subcutaneous route or by 5 centigrammes of the vaccine administered *per os* 5 times in 10 days.

Schlossmann, Tzekhnovitzer, Kirchner and Schneider were unable to confirm these observations.

Kraus and Gerlach have stated that the monkeys vaccinated by the subcutaneous route resist an infection by the application of virulent bacilli on the scarified skin of the eyebrows.

Meyer was able to keep his monkeys to be used for poliomyelitis experiments in good condition by B. C. G. vaccination, whilst the non-vaccinated monkeys contracted tuberculosis.

E. Küster and Elkes vaccinated the macacus *per os* with B. C. G. and observed a manifest resistance to a test injection.

A. Stanley Griffith has also stated that the vaccinated macacus showed a retardation of the progress of the test infection, the lesions being also less pronounced than in the controls.

Old and new Delhi were divided into areas. Medical officers in each local body were responsible for their respective areas. Fortnightly meetings of all the medical officers concerned were held at the Malaria Survey Office, Delhi, where Colonel Covell or Major Afridi, I.M.S. (special anti-malaria officer, Delhi), kept the medical officers fully posted with information about conditions prevailing in the various areas and about any danger spots. The Malaria Survey authorities collected all this information through their men who made daily surveys of all the areas. Different mosquito catching stations were fixed and insect catchers daily went round these stations. The spleen index of most of these areas was also recorded by the Malaria Survey staff.

A summary of the anti-malarial measures within the railway area is given below:—

(A) Measures taken before the onset of the monsoon.

(B) Measures taken after the rains had set in.

(A) *Measures taken before the onset of the monsoon.* Work under this heading was limited as the monsoon had already broken. However, measures were carried out on dry days as follows:—

(I) Filling up of depressions liable to hold rain water.

(II) Draining of bigger depressions containing water.

(III) Connecting up of rows, borrow pits or pools into one big borrow pit and suitably treating the water thus connected.

The main items requiring attention whilst treating such borrow pits were to see that they were entirely free from rank vegetation for about 10 feet around and that proper distribution of crude oil and cresol mixture by spraying from Planter's spray pumps was done. A few of these sprayers were kindly supplied to us by the Director, Malaria Survey of India. The mixture of crude oil and cresol used was the 25 per cent mixture, as suggested by the Director, Malaria Survey.

Paris green was not used very much because the borrow pits treated with this agent could not be easily inspected as it left hardly any tangible signs of the work done by the anti-malarial gang. The crude oil and cresol mixture however invariably left a layer which could easily be inspected any time after the pits had been treated with it. The only time Paris green mixture was employed was after heavy showers of rain which resulted in flooding the pits, as the Paris green mixture had a better effect at such times on account of the thick vegetation around.

Pyrethrum oil mixture was also used in borrow pits as a larvicide with good results.

Attention was paid to the drainage system and to the wells. Arrangements were made to cover all high service tanks and render them mosquito proof.

Pieces of machinery, scrap iron, etc., in railway yards were stacked so that no lodgements in which rain water might collect were left and in this connection the following instructions were issued:—

- (1) Corrugated iron sheets should be stored in a vertical plane or leaning upright.
- (2) Rails should be vertical in their long axis or placed horizontal in their natural position. The grooves should never be uppermost.
- (3) Pipe bends should have the two ends downwards.
- (4) Iron sleepers should have their concave surface downwards. Pot sleepers should be stored with the pot standing upside down.
- (5) Hollow engine parts, such as steam boxes, should not be placed so as to collect water.
- (6) Empty barrels, drums and buckets must always be stored inverted. Battery jars and cells should be stored mouths downwards.
- (7) Water-closet seats and commodes should be stored upside down.
- (8) Girders should not be on their sides.
- (9) In all such cases where an article is of such a nature as to make it impossible to prevent the accumulation of water, it should be stored in a covered shed.
- (10) Where scrap has been gathered to be sold by auction the material should be disposed of before the onset of the monsoon.

(B) Measures taken after the rains had set in—

- (1) Pyrethrum extract (sold under the proprietary name of Pyrocide 20) mixed with kerosene and pine oil (which had been found to be an effective insecticide spray for adult mosquitoes in Zulu huts in South Africa) was adopted in Delhi with encouraging results. The Director, Malaria Survey, instituted experiments with insecticides for destroying adult mosquitoes in the quarters of four different communities in the Delhi area. (One of the railway quarters at Subzi Mandhi.) One gallon of pyrocide was mixed with 19 gallons of kerosene oil and one gallon of pine oil. This mixture was used for spraying inside the railway quarters. A small 'Flit' pump was used for the purpose. The quarters were properly closed

and no chinks or other possible outlets for mosquitoes were left whilst the spraying was going on. The results were very satisfactory.

- (2) A 'dry day' was observed and the following notices were issued to occupants of all railway bungalows, quarters, etc.:—

'Anti-Malarial Measures, Delhi Area

In the interests of the health of railway employees, their families and the general public, it is expedient to stop mosquito breeding within railway area by observance of Sunday as "dry day" on which day all bungalow residents, heads of offices and other subordinates will inspect their houses, outhouses, stables and compounds, etc., for breeding places and will look carefully for tins, bottles containing water, choked drains, *gharras*, sumps outside bath houses and in the garden—these will be emptied and thoroughly dried by 9 a.m. on Sunday and allowed to remain so until inspected by the anti-malaria staff the same afternoon.

Mention of interesting experiments with a man trap may be made here. The experiments are interesting in so far as they afford information as regards the time of evening or night when really the dangerous type of mosquitoes bite human beings and thus one can find out the time when one should take necessary precautions. The procedure was that an observer lay on a bed placed in the open in a bungalow compound. The bed was fitted with two mosquito nets, the inner one being tucked in closely around the bed, and the outer one being capable of being lowered by the observer when he saw any mosquitoes alighting on the external surface of the inner net. An assistant then came and collected the mosquitoes. The outer net was 10' X 7' X 7' and was wide enough to allow the assistant easily to go round the bed in order to catch the mosquitoes which had been trapped by lowering it. Collections were made at least every two hours, the first being at 8 p.m. and the last at 6 a.m. The experiments were repeated on a number of nights but could not be carried out except when the weather was clear and there was no wind.

My thanks are due to the chief medical and health officer, N. W. R., Lahore, for permission to publish this article.

A Mirror of Hospital Practice

ANGINAL PAIN IN A CASE OF MALARIA

By K. D. MANOHAR, M.D.
Pathology School, G. M. College, Bombay

and
K. K. KHOSRAWY, M.D., B.S.
House Physician, J. J. Hospital, Bombay.

MALARIA has been mentioned as one of the causes of angina pectoris. P. Retzck in a series of lectures on angina pectoris described some characteristic cases of

malarial angina and quoted the opinion of Gaskell that 4 per cent of malarial cases result in cardiac death due to coronary thrombosis. This thrombosis may be precipitated by an acute attack, previous chronic malaria having produced endarteritis.

The incidence observed is very high and is probably based on cases infected with Italian or African strains of *Plasmodium falciparum*. James and others (1932), on observations of

several strains used for therapeutic malaria, had also come to the conclusion that Indian strains of *P. falciparum* were much less likely to produce severe complications than the other strains. Bass had described malarial pseudo-angina. On the other hand, although angina may not be prominent, severe cardiac involvement may be the actual cause of death in many comatose cases of malaria, which are generally put down as cerebral malaria. Cases have been observed in which a deep coma was accompanied by marked cyanosis, enlarged soft liver and rapid feeble heart. The cerebro-spinal fluid was not under tension and showed no increase in cells or proteins. In spite of quinine

Another affection which is capable of producing anginal symptoms and is found in cases of chronic malaria is dilatation of the first part of the aorta. Benhamou (1926) and Giauni (1929) who have noted such dilatations are emphatic that it is not due to aortitis. Yet it is likely that acute thrombosis of the *vasa vasorum* of the aorta may produce anginal symptoms. Very few electrocardiographic studies in malaria have been published. Although some abnormalities have been noticed characteristic curves of coronary thrombosis have not been obtained.

The patient, G. S., a railway coolie, aged 35, was referred on the 18th May, 1936, to the hospital by the

Lead I.

Lead II.

Lead III.

injections these cases have rapidly sunk and died, strongly suggesting a cardiac failure rather than a medullary one.

Von Engel (1925) has described a similar case of a male, aged 24, who died in coma with a pulse rate of 130 per minute and very feeble heart sounds. Sections of the heart showed severe malarial thrombosis and cloudy degeneration of the muscle.

Brosius (1925) has also described a case of cardiac malaria in which marked cloudy swelling of cardiac muscle resembling that of acute diphtheria was found at autopsy.

Micheletti (1929) has described vascular thrombosis with fragmentation and necrosis of the cardiac muscle.

railway doctor for severe pain in the precordial region, palpitation and breathlessness of sudden onset. He had fever with rigors for two weeks, fifteen days before but was afebrile and able to attend to his work till the onset of pain.

Examination.—Marked restlessness, eyes deeply congested, no rigidity of neck. Kernig's sign negative. Abdomen slightly full and tympanitic, spleen not palpable.

Chest.—Pain in the lower sternal and epigastric region. No radiation. Lungs—prolonged expiration with rhonchi. Pulse—120 per minute. Respiration—40 per minute. Temperature—101° F. Blood pressure 90/40. Leucocytes—3,000 per c.mm. Differential count—polymorphonuclears 62, eosinophiles 4, hyalin 8 and lymphocytes 26 per cent. Blood film showed very large number of *P. falciparum* gametocytes. Ring forms were comparatively few. Widal reaction—negative, blood culture for bacteria—negative. Wassermann reaction—strongly

positive. The temperature rose to 104°F. No coma; breathlessness increased giving rise to cyanosis. Quinine was given intravenously.

Next day the temperature was normal. The pain completely disappeared. Heart sounds feeble. Lungs clear. The temperature showed two lesser elevations on two more periodic intervals. The pulse rate was still about 120 per minute though the temperature was normal.

On the 25th May, 1936, the patient had another attack of pain and breathlessness. Examination revealed impaired percussion note, feeble breath sounds and fine râles at the left base in the axillary region. There was no significant rise of temperature. The area spread, and on the 28th a distinct rub was felt over the affected area. All clinical signs as well as breathlessness completely disappeared next day. Further progress was uneventful. The blood pressure on the 4th June was 100/60 and the pulse 90 per minute. The pressure after five days was 110/60. Wassermann reaction repeated on the 9th was faintly positive.

There was no history of syphilitic infection nor any clinical manifestations of it. The first positive Wassermann reaction may be that rare condition, a false positive Wassermann reaction, due to malaria.

An electrocardiogram was taken three weeks after the onset, when the systolic blood pressure was 110, and the pulse rate 80 per minute.

Lead I showed a distinct low voltage with a well-marked plateau after the S.

Lead II showed a sharp Q, a biphasic RS and a distinct slurring of S in places, almost a bifurcation and a prominent angular T.

Lead III was similar to lead II, but less prominent.

It distinctly pointed to cardiac infarction of few days' standing. If it had been possible to take the earlier records, the changes would have been still more striking.

Discussion

The pneumonic signs are suggestive of several conditions. Like the heart condition they might be of malarial origin. Karve (1926) from Kenya has described primary and secondary pneumonias of malarial origin. These, as in the present case, are characterized by uncontrollable pleural pain, transitional râles and short duration. But the onset of the symptoms after the disappearance of the parasites from the blood makes the malarial origin unlikely.

A ward infection can be ruled out by the extremely short duration of the signs and symptoms and absence of leucocytosis.

Reflex atelectasis with formation of mucus plugs similar to post-operative pneumonia has been described following an infarction of the heart. Donzelot (1934) has described fleeting pneumonic signs as a late complication of infarction of the heart due to embolic showers. The lung condition was probably one of the last two.

Summary

A case is described in which severe anginal pain, cyanosis, rapid pulse and low blood pressure marked the onset of a malarial attack.

The infection was not heavy and there was no evidence of thrombosis in other organs such as the brain.

The pulse rate remained rapid and the blood pressure was low for two weeks after the attack.

Acute pneumonic symptoms of very short duration occurred soon after, but these are not considered to be of malarial origin.

The Wassermann reaction was positive during the acute attack.

Acknowledgments

Our thanks are due to Lieut.-Colonel S. S. Vazifdar for his kind permission to publish this case and to Dr. B. B. Yodh who kindly undertook the electrocardiographic investigations.

PRONTOSIL IN PYELO-CYSTITIS AND ERYSIPELAS

By Y. SURYANARAYANA RAO, L.M.P., L.T.M.

Assistant to the First Physician, and Medical Registrar, Government Royapuram Hospital, Madras, and Assistant Lecturer in Medicine, Stanley Medical School, Madras

IN view of the encouraging reports that are being published in the medical journals about the action of prontosil in streptococcal infections, it may be of interest to record its beneficial action in the following two cases, one of pyelo-cystitis and the other of erysipelas, that were treated in the Government Royapuram Hospital, Madras, four months ago.

1. *A case of pyelo-cystitis.*—A patient, a male, aged about 28 years, was admitted into the above Hospital on the 16th February, 1937, with a history of fever and pain over the hypogastric region for eight days.

There was nothing worthy of note in the family history. His habits were regular; he neither drinks nor smokes. No history of exposure to any venereal infection.

As regards his previous history, he had occasional attacks of burning sensation during and after passing urine in the year 1928.

Present history.—On the night of 8th February, 1937, while he was travelling in a train, he had high fever which rose to 104°F. by the next evening. Thinking it to be malaria, he took 20 grs. of quinine sulphate that day. The temperature came down to normal on the morning of the 10th; from the evening, however, he began to pass urine in small quantities frequently accompanied by burning sensation and griping pain. He had also pain in the loins.

[MARCH, 1938]

Present condition.—The patient was a fairly well nourished young man. He was having a temperature ranging between 102° and 104°F. Peripheral blood did not show any malarial parasite. There was a slight increase of polymorphonuclear leucocytes.

24th, and 26th. From the 20th, he was also put on mandelic acid treatment. It was given in the form of elixir ammonium mandelate. When the reaction of the urine was found to be not sufficiently acid for the drug to act, by the methyl red test, the patient was given

Urinary system.—There was pain during micturition. There was no urethral discharge, even after prostatic massage. The reaction of the urine was alkaline, slight trace of albumin was present, no sugar, and the urine was cloudy in appearance. The urinary deposit under the microscope contained plenty of pus cells and a few red blood cells. There were no casts. A three-glass test revealed that all the specimens were uniformly cloudy in appearance and contained pus cells. There

additional doses of ammonium chloride by mouth. This at once increased his burning sensation while passing urine, but it did not bring the reaction of his urine anywhere in the neighbourhood of 5.3 pH which is necessary for the success of mandelic acid treatment. So this treatment had to be discontinued. In spite of five intravenous injections of cyclotropine, the temperature did not show any sign of abatement. Then on the 28th the patient was given an intramuscular injection of 5 c.cm.

was some granular debris present. The deposit also showed some epithelial cells from the pelvis of the kidney and also from the urinary bladder. The urine on culture showed *Bacillus coli*.

On the 18th February 5 c.cm. of cyclotropine was given intravenously and it was repeated on the 20th, 22nd,

of prontosil. Since that date, he showed steady improvement both as regards the fall of temperature and in the general and local symptoms. The burning sensation in the urine decreased considerably. On the 2nd and 4th March, prontosil was repeated. The temperature came down to normal and kept normal till he

was discharged on 15th March, 1937. The patient had no burning sensation. The urine was clear and did not contain any pus cells nor any *Bacillus coli*.

This case shows the beneficial effect of prontosil in infections other than streptococcal.

2. *A case of erysipelas*.—A female, married, aged about 18 years, was admitted into the Government Royapuram Hospital, on the 8th February, 1937, for fever and headache for seven days. Her previous history was that she had fever for about eight days a month back; and that she was in this hospital for fibrosis of the lungs one and a half months back.

The present complaint started with high fever which was continuous for the past seven days. She was a thin individual and of delicate health. Pulse was rapid but full. Liver and spleen were not enlarged. Urine was quite normal. Respiratory system did not show anything in particular beyond a few crepitations here and there. Peripheral blood did not show any malarial parasites but there was distinct increase of polymorphonuclear cells. On the day of admission she was found to have an erythematous patch very slightly raised above the surface, about two inches in diameter, over the front of lower third of the right leg. The part was tender and painful. Thinking it might be localized lymphangitis, lead and opium lotion was applied. But the fever continued high and the local lesion was increasing. Widal reaction for typhoid group of bacilli was negative. As the swelling and redness in the right leg began to increase and the temperature persisted, 10 c.cm. of antistreptococcus serum was given intramuscularly on the 11th. This also did not have any effect, either on the temperature or on the local condition. So, on the 13th, prontosil 5 c.cm. was given intramuscularly. By this time the local redness had spread up to the knee, and the patient was in a toxic state. There was retention of urine and she had to be catheterized. Next day, there was a definite improvement both in the general and local condition. Prontosil was repeated on the 15th and 17th. The temperature came down to normal, and the local condition was definitely better. The patient was given two more injections on the 19th and 21st. By this time the erysipelas inflammation had completely disappeared and the temperature came down to normal, and since then the patient made an uneventful recovery and was discharged cured on the 3rd March.

The above two cases were admitted under Captain Rao Bahadur P. Krishnaswami, B.A., M.B., C.M., M.B.C.P., first physician and superintendent of the hospital, and my grateful thanks are due to him for going through these notes and also for permission to publish them.

[Note.—In case 1 the temperature might possibly have subsided without prontosil.—EDITOR, I. M. G.]

SALYRGAN IN PHLEGMASIA ALBA DOLENS

By R. L. SONI, M.B., B.S., F.R.H.S.

Paungde and Nattalin, Burma

ENCOURAGED by the favourable results produced by salyrgan in the treatment of various generalized and localized cedemas, I was led to use the drug in a case of phlegmasia alba dolens, the thrombotic form of which is essentially a variety of localized cedema brought about by femoral thrombosis towards the end of the puerperium. The beneficial influence exerted

by the drug in relieving the condition prompts me to record the case :—

Mrs. K., a banker's wife, aged 21, had her first confinement on the 5th April, 1937. The delivery was complicated by an extremely unusual obstetric emergency, namely separated symphysis pubis, and so naturally damage to the soft parts was great. The child was born dead, hæmorrhage was severe, the perineal tear was large and deep reaching the rectum, and anteriorly a large retro-pubic niche was formed by the separation of soft structures which had fallen back.

The puerperium obviously could not be uneventful. She had a very bad time but serum, prontosil, liver preparations, tonics together with properly planned local dressings and careful nursing, controlled the situation. On the 14th day she had serum sickness which was followed by a generalized mild cedema. Anæmia which had developed during the puerperium was severe. Calcium, sulphate of iron, campolon and oral hepatex were used. Cedema rapidly cleared in the rest of the body but the left foot continued getting worse. On the 20th day the foot was markedly swollen and pitted on pressure. Next day the swelling extended higher and in another day the thigh was tense. Temperature rose a little and there was slight rigor, but pain in the calf and thigh was intense and even slight movements were resented. On the 23rd day the foot and leg were large and still pitted on pressure; the thigh was swollen, tense, hard and very painful. Novalgin one to two tablets a day in divided doses was given. The leg was fomented, gently wrapped in cotton, put at rest on pillows and immobilized with side-pillows. In addition to the blood-building measures already in progress she was given salyrgan 1 c.cm. intramuscularly, with the idea of draining away the localized cedema. The response was gratifying inasmuch as a profuse flow of urine brought about an appreciable reduction of the cedema of the foot and leg within 24 hours, though the swelling of the thigh did not appear to be noticeably affected. The pain was less relieved than the cedema. Encouraged by the result another injection of salyrgan was given on the 26th day. It was followed by a steady improvement, but on the 29th day though the temperature came to normal and pain and hard stiff swelling of the thigh was getting less, cedema of the foot was once again noticed. She was given ammonium chloride grs. 15, t.d.s., and with the morning dose salyrgan was administered orally (1 c.cm. of a 10 per cent solution) on the 30th and 31st days and 2 c.cm. on the 32nd and 33rd days. By the 35th day cedema of the foot had disappeared and the tense swelling of the thigh had gone down to a marked extent. By the 40th day even the thigh was clear.

Comments.—In the presence of anæmia, puerperal sepsis, pelvic cellulitis and other complications it was not surprising that phlegmasia alba dolens should occur. In this case the thrombotic and lymphatic forms co-existed. The reduction in the cedema of the foot and leg that followed the administration of salyrgan by injection was marked. That it was brought about by salyrgan was clear from the profuse diuresis that attended its use. To control the cedema that recurred on the foot it was decided to try the drug orally, as the patient, having become tired of so many injections, resented even ordinary pricks at this stage. Salyrgan administered together with ammonium chloride brought about a rapid improvement in four days. The efficiency of salyrgan appears to be not appreciably depreciated by oral administration. Fleckseder (1931) used it orally and rectally with good results.

The condition of phlegmasia alba dolens is known to take several weeks and sometimes months to clear. In this case it took only 20 days. Though the associated measures (nursing, campolon, tonics, etc.) must have done their respective parts, the effect produced by salyrgan in draining the œdema was definite and it appears was a useful factor in accelerating the cure.

Summary.—A case is recorded of phlegmasia alba dolens in which salyrgan was administered parenterally and orally with benefit.

A CASE OF SCARLET FEVER

By BALKRISHNA N. MEHTA, M.B., B.S.

Medical Officer, Juvansinhji Dispensary, Bhavnagar

ON the tenth day of illness I was called in consultation to see a female patient aged about 20 years.

Previous history.—Ten days ago she felt ill and had pain in the throat and was feverish. Next day an eruption was noticed on the face. It was red, punctate and then confluent and spread all over the body within four days. Desquamation started on the eighth day.

She was in bed with a temperature of 101°F. and pulse 120 per minute. The rash spread from head to foot and desquamation had already started. For the most part it consisted of fine scales, while on the palms and soles large flakes—complete glove-like casts—were about to be thrown off. The pharynx was very congested. The tongue was thickly furred and flabby, but not typical of scarlet fever. The lymphatic glands under the right jaw were enlarged and tender; they had been enlarged on both sides, but the left ones had subsided. No enlargement of the liver or spleen was felt. There was no respiratory complication. Cough was slight and pharyngeal in character. There was a great deal of itching all over the body. The maximum temperature was 104°F. The patient was delirious at night. There was a history of passing blood in the urine. The bowels were constipated.

The urine which was examined on the twentieth day contained no albumin or casts. The temperature gradually came down to normal on the twenty-second day; however, it remained fluctuating between 98°F. to 99°F. for about eight days more. Prontosil by mouth was given from the fifteenth day.

The patient had had measles in her youth. The diagnosis of scarlet fever was made from the character of the onset, the type of rash and its desquamation.

During twenty-four years' practice I have only seen three cases of scarlet fever; all were females. The first one, a Parsi woman, was seen ten years ago and survived. The second one, which proved fatal, was seen last year.

[*Note.*—Although very suggestive it is possible that this disease was not scarlet fever because it is atypical in several of its manifestations. It may have been a toxic erythema induced by a septic infection of the throat. If other similar cases had been noted in the

district at the time the diagnosis of scarlet fever would have been rendered much more likely. It is difficult to understand how a single case of a very infectious disease could arise without a history of contact with earlier cases and how it was not followed by others, especially in a community that would almost certainly be highly susceptible.—Editor, I. M. G.]

PROBABLE RING CARCINOMA OF THE DESCENDING COLON; MANGO FIBRES OBSTRUCTING THE RING AND CAUSING COMPLETE OBSTRUCTION

By S. R. GORE, L.M. & S.

Honorary Surgeon and President, The Hubli Co-operative Hospital Society, Hubli

N. N. P., age 45, was admitted into the hospital on 16th June, 1937, for intestinal obstruction.

History.—She had pain in the left iliac region on 12th June, 1937. The pain was attended with vomiting and constipation. Since 14th June she had absolute constipation. She was given a soap-and-water enema by the sub-assistant surgeon of the nearest dispensary when she passed a little hard stool; after this there was no further stool or passage of flatus.

Her abdomen was distended but not tense when she was admitted. Temperature—98.4°F., pulse—95, and respiration—30 per minute. Soap-and-water enema given in the hospital had no effect.

Immediate laparotomy was done under spinal anaesthesia and the cause of the obstruction was found to be a hard ring carcinoma at the junction of the descending colon and the sigmoid. The constriction was band-like and hard and it was found to be connected with some enlarged glands adjacent to the mesentery. The gut proximal to the stricture was enormously distended. As it was found impossible to do a side-to-side anastomosis a resection of the tumour with the glands *en masse* and an end-to-end anastomosis were done, after making an incision on the antimesenteric border of the collapsed sigmoid to make it fit the distended gut above the stricture.

The patient made an uninterrupted recovery and was discharged on the 9th July, 1937. She has had no more trouble up to the present and she attends the outpatient department occasionally for inspection.

The specimen is preserved. On inspection, it was found that a mass of mango fibres was blocking the constricted lumen of the gut which was just large enough to admit a lead pencil. There was no history of any pain or other symptoms previously and the patient considered herself quite normal up to 12th June, 1937, when pain started. The inner surface of the ring is not ulcerated. The general condition of the patient was quite good, there was not the least trace of cachexia. I have diagnosed this as cancer on account of its hardness and the hard associated glands. There being no means for making a section, microscopic pathological investigation could not be carried out*.

*It should be an easy matter to send the whole or part of the tumour to a pathological laboratory for confirmation of the diagnosis.—Editor, I. M. G.

DRY CUPPING AND ITS SEQUEL*

By A. K. DUTT GUPTA, M.D., D.T.M.

Resident Surgeon, Medical College Hospitals, Calcutta

THE patient, a female, aged 30 years, was in the habit of burning paper and charcoal (*Tika*) inside a large *lotta* and putting it, mouth downwards, over the lower part of the abdomen for relief of pain. This she did many times, kept it on for 2 to 3 hours and removed it without difficulty. On this occasion she could not get it off and after herself trying for

The woman came to the hospital two days later. The skin of the abdomen, as seen through the opening, was bluish with one or two black spots. The swelling was very tense and cedematous and projected for about four inches above the skin level. With extreme difficulty a finger could be pushed between the neck of the pot and the swelling but there was a fear that if distended gut was inside the swelling it might burst. It was impossible to divide the rim of the pot. The hospital *mistri* was called in to divide the vessel into two halves along the opening already present; his instruments failed to make much impression, but an

Fig. 1.—Before removal the tense swelling is not so apparent due to want of illumination inside. Most of the black area is the affected part.

Fig. 2.—After removal—showing the affected part.

several hours called in assistance. It was stated that the combined efforts of three men failed to remove it. Next they called in a doctor, who advised that an opening should be made in the pot to let in air. A cut about half an inch in length was made but still the pot could not be removed. After this an attempt was made to divide the *lotta* into two portions by a horizontal cut, but it failed as the tools available were not good and the bowl was very thick.

opening large enough to admit the fingers was made (figure 1).

The patient was anaesthetized and a quantity of thick sterile oil was poured into the pot over the abdominal swelling. A thick pair of linen gloves were put on over the ordinary rubber gloves and a finger was insinuated externally between the swelling and the fairly sharp and irregular rim of the pot, and another finger was inserted through the opening to help the other finger. After half an hour of careful manipulation the pot was removed. The area of the skin that

* Abridged by the Editor.

was inside the pot measured 8 inches by 6 inches (figure 2). The patient made an uneventful recovery.

The pot weighed 2 pounds, 11 ounces, height $6\frac{1}{2}$ inches, circumference $18\frac{1}{2}$ inches. The mouth was $4\frac{1}{4}$ inches and the rim (narrowest part) $2\frac{5}{8}$ inches in diameter. The opening made in the side was $4\frac{3}{4}$ inches in length.

A SUB-PHRENIC ABSCESS

By S. C. DAS GUPTA, M.B., B.S.

Assistant Surgeon, Jamshedpur

A MALE of poor physique, aged about 22 years, was admitted into the Jamshedpur Sub-divisional Hospital on 27th October, 1937, for treatment of 'acute abdomen' with fever, vomiting and jaundice. His condition was not good at the time of admission. He gave a history of dysentery some time back but nothing else of importance.

He had an abdominal facies, and a hard mass which appeared to be continuous with the liver was found in the epigastric region. It was tender and movable with respiration. The liver dullness extended upwards to the level of the 5th rib posteriorly on the right side.

Temperature 99°F ., pulse feeble and rapid, and respiration 21 per minute.

Blood examination:—Total leucocytes—24,000. Differential count—Polymorphonuclears—95 per cent. Small mononuclears—5 per cent. Large mononuclears—nil. Eosinophils—nil.

A provisional diagnosis of liver abscess was made and an exploratory laparotomy was decided upon but could not be performed as the condition of the patient was not good enough.

At 4 p.m. of the same day, he complained of a very sharp pain in the abdomen, and in about 20 minutes' time he collapsed and died.

Post-mortem examination: Clots of blood mixed with yellowish-white pus were found mostly in the upper abdomen behind the stomach and to a less extent over the intestines. All the structures were matted together. No lesion was found either in the liver, stomach, or other organs in the neighbourhood. There was ulceration on the lower part of the posterior surface of the left lobe of the liver but no abscess cavity.

The point of interest of the case is its close resemblance to liver abscess.

A RETRO-PERITONEAL SUPPURATING DERMOID IN THE REGION OF THE KIDNEY

By M. G. KINI, M.C., M.B., M.Ch. (Orth.), F.R.C.S.E.

Surgeon

and

P. KESAVASWAMI

Radiologist

King George Hospital, Vizagapatam (S. India)

RETRO-PERITONEAL dermoids in the region of the kidney are rare and their mode of origin is speculative. Ewing classifies them under 3 heads:—

- (1) Tridermal teratomas.
- (2) Epidermal rests derived from the Wolffian duct.
- (3) True dermoids derived from imperfect closure of abdominal folds.

A female child was admitted in 1932 with a sinus discharging pus on the left side of the back of two years' duration. The sinus was found to go to the region of the kidney and the pus had a peculiar mawkish odour. On x-ray examination, in the region of the kidney a dense crescentic shadow was found below the first rib on the left side. Her kidney function was found to be within normal limits. On operation the sinus was found to lead to the region of the kidney and on going deeper hairs were found. A diagnosis of a dermoid cyst was made and it was removed. The dissection of the cyst

Fig. 1.—The radiograph of the lower thorax and abdomen showing a dense shadow in the region of the left kidney.

Fig. 2.—The photograph of the specimen removed at operation.

was difficult as it was fixed to the posterior abdominal wall and diaphragm.

On removal, the tumour was found to be kidney-shaped measuring three inches in length, two inches in width and two inches in thickness. The major part of the tumour contained fat and weighed three and a half ounces. A piece of calcified cartilage about the size of a quarter of a circle of two inches radius was also found. The upper and lower ends of the tumour consisted of skin with long hairs hanging from the ends. The patient was discharged with a sinus and she reported subsequently that the sinus took one year to heal and now it is completely healed and she is keeping perfect health.

Indian Medical Gazette

MARCH

DISASTER AND ITS MORAL

At a time when daily newspaper reports of air raids on open towns and the deaths of hundreds of innocent victims of internecine wars in distant-parts of the world are almost ignored, it is interesting to study what will stir the imagination of the public and what particular kind of disaster is required to arouse their indignation.

A report of thousands of deaths from chronic disease certainly will not, though an epidemic may, for as long as the death and incidence rate continues to rise. Disasters to air-liners will affect the tranquillity of comparatively few, in fact such news rather pleases the majority, as it gives them an opportunity of reiterating their already expressed intention of never travelling by air and, by comparison, gives them an extra feeling of personal security; more will be alarmed at the loss of an ocean-going liner; but when a railway train leaves the lines a public enquiry is instantly demanded, and for months is a subject of double-column headline news. Yet, what would have happened had by some pure chance such a disaster been averted at the last minute? Though the bad organization, the defective track, or the dangerous condition of the rolling stock or engine was still known to exist, the incident might have been given half-a-dozen lines at the bottom of the news page and possibly have led to a departmental enquiry, but no more. No, the days of human sacrifice are not past, *vox populi* demands inexorably the sacrifice of far more human victims than any of the ancient gods, before it will be stirred into action, and further it demands that its victims shall be killed in dramatic circumstances.

We have repeatedly drawn attention to the dangers associated with the present uncontrolled state of the drug trade in this country. A state of affairs in which any unprincipled person can manufacture and sell as a nostrum to a gullible public almost any worthless or dangerous substance. He does not have to satisfy anyone even as to its possible efficacy, or, still worse, as to its safety; he can maintain secrecy as to its content or even make misleading statements about this. Such nostrum can be sold directly to the public without a prescription from or reference to a member of the medical profession. In fact, the stage is set for a first-rate tragedy, but until it is played right through and the curtain has fallen on the bloody scene, with the bodies all laid out in a row and counted, we fear the public imagination will not be moved, and no action will be taken.

It is not possible for us to learn something from other people's mistakes, or must the disaster occur at our own doors? There have been casual references in the public press in this country to the 'sulfanilamide elixir' disaster in the United States, an incident which has certainly made a deep impression on the public in that country. The story is, shortly, as follows:—A firm of drug manufacturers prepared a mixture which they labelled, ironically, 'elixir of sulfanilamide', and issued it to the public through pharmacists and the medical profession in at least a dozen of the southern states of America; of those who took this mixture on their own initiative or on the advice of their doctor, up to 11th November last year, 73 had died, apparently as a direct result of taking this 'elixir'.

After the first few patients had died and suspicions were aroused as to the cause of their deaths, every endeavour was made, by extensive publicity in the press and by broadcasting, to warn the public and to trace the bottles of 'elixir' that had been issued, but it was too late to prevent the death roll from reaching these considerable proportions.

Sulphanilamide is a potent substance and it has been repeatedly pointed out that, in our present state of knowledge regarding its reactions when combined with other drugs, it should be administered alone or with bicarbonate of soda, but the pharmacological investigations that were immediately instituted showed that it was not the sulphanilamide itself, which had in this instance undergone no detrimental change, but the vehicle in which it was dissolved to make the 'elixir' that was at fault; the manufacturers had used di-ethyl glycol, a substance which hitherto has not been used for oral administration and is known to be toxic in the doses they advocated, as reference to chemical and medical literature would have shown them had they investigated the matter. These pharmacological experiments, which could just as well have been carried out by the manufacturers themselves, before they issued their 'elixir' to the public, showed that di-ethyl glycol alone, without the addition of sulphanilamide, given in comparable doses to animals produced death and pathological lesions which were parallel to those produced by the 'elixir' in man.

Is it conceivable that any firm of drug manufacturers for the sake of monetary gain could be so callous as to prepare, issue, recommend the public to take, and importune doctors to prescribe a substance whose death-dealing properties they had made no attempt to investigate? Is it conceivable that the law is so inadequate that it does not compel drug manufacturers to test such drugs before they issue them to a trusting public? Is it conceivable that any qualified chemist should be so irresponsible as to hand over to a customer this potential—as far as he knew, and in fact actual

—poison? And, worst of all, is it conceivable that any medical man should be so unscientific and so utterly negligent of his patient's interests as to give him or recommend him to take a preparation, not only the therapeutic properties but, the very composition of which he was in entire ignorance?

The answer we are afraid is in each instance in the affirmative. Inconceivable as it may seem, it was so in America and it is so to-day and every day in India. The unscrupulous drug purveyor not only exists, he flourishes. The law of the land gives us no protection against his dishonest and dangerous practices, whether he prepares his drugs in this country or sends them to us from abroad. How many pharmacists question the *bona fides* of the drugs they sell provided they are in an attractive and fresh packing? Does every physician take the trouble to ascertain that the brands he is prescribing have been properly tested, do what they are claimed to do, and do not contain some toxic ingredient. If a doctor prescribes a pharmacopœial preparation and the dispenser gives the patient something else, then admittedly it is not the doctor's fault, but if he prescribes a patent medicine, a secret nostrum or even a non-pharmacopœial proprietary preparation, just because by the morning post he had received a cleverly-worded pamphlet, which hailed it as a great scientific discovery, or because some loquacious and plausible young man had thrust a sample into his hands, then he is immediately taking responsibility on his own shoulders.

This he may be quite prepared and quite right to do; so many of our most valuable drugs are proprietary preparations, but these are accepted drugs that have been scientifically tested by independent workers and though not in the *British Pharmacopœia* are to be found in the *Codex* and such publications as the *Extra Pharmacopœia*; they are made and put on the market by reliable firms who have large testing and research laboratories behind them.

What then are we to do? We can but add our voices to the general demand that legislation with regard to the control of the drug trade be pushed forward with the utmost expedition; the bill that is at present before the central legislature is on the right lines but only touches one aspect of the matter and future legislation will have to be much more comprehensive. In the meanwhile, as the physician cannot test for himself every drug that he prescribes, he must limit his prescriptions to the simpler pharmacopœial preparations—and even these are not adequately protected in this country—or use the drugs made by firms with established reputations.

There are many commercial organizations, in this and in other countries, who have made great contributions to pharmacological research and who are far too jealous of their good names to risk putting on the market any drug that has not been most elaborately tested from all points of view, and in the absence of any state protection the physician is compelled to turn to such organizations to safeguard his patients' and his own interests.

Special Article

THE SPECIFIC TREATMENT OF MALARIA

(BEING A RÉSUMÉ OF A LECTURE)

By L. EVERARD NAPIER, M.R.C.P. (Lond.)

Professor of Tropical Medicine

School of Tropical Medicine, Calcutta

THE first point to be realized is that the treatment of malaria is not a subject about which one can be too dogmatic. The writer's experience has been mainly in this country, but he has visited a number of other eastern countries, studied the work of others in these countries and realizes that in no two countries is the problem really the same. This paper will therefore be applicable mainly to the treatment in India of malaria caused by Indian strains of plasmodium.

Let us first of all analyse our aims in treatment, and we must consider treatment in the widest sense, that is, treatment to prevent, as well as to cure, the disease. The objects that we hope to achieve by specific drug treatment—

and it is only this aspect of treatment that will be dealt with—can be placed under five headings:—

(i) *True causal prophylaxis*; by the administration to the person who is exposed to infection of a drug that will destroy the sporozoites injected by the mosquito before they enter the red cell and commence their intra-corporal cycle.

There is at present no drug which will achieve this. Ten grains of quinine given daily for five days before and nine days after a person has been infected by a mosquito will not prevent the development of the parasite, nor will atebain in full therapeutic doses followed by a daily dose of 0.1 gramme. And in an experiment carried out in London, in which some half-dozen well-known malaria workers took part, three daily doses of 0.02 gramme of plasmochin (a dose which will sometimes produce toxic symptoms) were given for one day before and six days after the infective mosquito bite, and yet five out of six of these men became infected.

The introduction of a drug that will act on the sporozoites will mark a great advance in malaria therapy.

(ii) *Clinical prophylaxis*; by the administration of a drug that will prevent the infected person from suffering from an attack of clinical malaria, but without necessarily destroying all parasites in that patient.

Now this can be done. A dose of 0.2 gramme (three grains) of atebtrin given twice a week, or a daily dose of six grains (five grains are sometimes insufficient) of quinine will usually keep a person free from clinical malaria, even in a very malarious place, for an almost indefinite period. A large-scale experiment has recently been carried out in Malaya in an estate labour

fever as long as the atebtrin dosage was continued; this dosage did not, however, produce true causal prophylaxis and did not eradicate the malarial infection completely, but kept it at a sub-clinical level, so that when the drug was discontinued a very large number of the patients suffered a clinical attack of malaria almost immediately and nearly 80 per cent within two months.

This is shown in figure 2 below which gives the malaria incidence month by month for more than a year. It will be seen that, when in the control group there were nearly forty cases monthly, in the atebtrin group there were none, or only one or two. However, directly the prophylactic treatment was withdrawn the

Fig. 1.—Immediate effect of prophylactic measures.

force. In one group every one was given atebtrin on two consecutive days during the week—adults had a dose of 0.2 gramme each day and children correspondingly small doses, as shown in the table below. In another group six grains of quinine were given daily to adults, and children were given smaller amounts, as shown in the table.

Ages : years	Atebtrin : grammes	
1 to 2	0.025	or 0.1 g. euquinine (1½ grains).
3 to 4	0.05	or 0.2 g. euquinine (3 grains).
5 to 6	0.075	
7 to 8	0.1	
9 to 10	0.125	or 0.2 g. quinine bihydrochloride.
11 to 12	0.15	
13 to 16	0.175	or 0.4 g. quinine bihydrochloride.

A third, control, group received no specific treatment. The results of this prophylactic treatment are shown in the figures (1 and 2) (Field, Niven and Hodgkin, 1937).

It will be seen that in the atebtrin series the malaria was controlled almost immediately and only an occasional case occurred: in the quinine series the control of the malaria was slower but eventually the fever was largely controlled.

The important point however is that, even in the atebtrin group, they were only kept free from

incidence in the atebtrin group rose to 37 and was actually higher than in the control group.

(iii) *Treatment of the clinical attack*.—In the very great majority of cases this can be brought about by the administration of atebtrin, quinine, or standardized cinchona febrifuge (B. P. totaquina standard) by the mouth.

If atebtrin is used 0.1 gramme (or 1½ grains) should be given three times a day for five days—or in severe malignant tertian infections this may be continued for seven days, but not longer.

The daily dosage for children should be :—

1 to 2 years	.. 0.05 gramme
3 to 4 "	.. 0.075 "
5 to 8 "	.. 0.1 "
9 to 12 "	.. 0.2 "
13 to 16 "	.. 0.25 "

If cinchona or quinine are given, the prescriptions should be :—

R	Totaquinæ (or cinchona febrifuge)	gr. x
	Acidi sulphatis dil.	.. min. xx
	Magnesi sulphatis	.. gr. xxx
	Aquam chlorformi ad	.. 5i
or		
R	Quininæ sulphatis	.. gr. x
	Acidi citratis	.. gr. xx
	Aquam chlorformi ad	.. 5i

One of these should be given twice daily in benign tertian infections and three times daily in malignant tertian infections and this dosage should be continued for seven days.

In the very great majority of instances oral administrations will be sufficient and effective. The reason for this is that when the drug is given by the mouth to a healthy person it is absorbed by the gastric mucosa immediately, and within about half an hour it will have appeared in the urine. By whatever route it is given, it will not reach the systemic blood faster than this. There are, however, some cases in which there is no response to oral administration and the reasons for this are as follows:—

(1) Absence, or a shortage, of quinine in the so-called quinine mixture. This may be due to

Test for quinine in mixture

The reagent is made up as follows:—Pure phosphotungstic acid—1 ounce, dilute sulphuric acid—5 ounces and rectified spirit—12 ounces. Place 25 c.cm. of the reagent into each of two narrow tubes; add to one 0.25 c.cm. of the quinine solution to be tested and to the other 0.25 c.cm. of a control quinine containing the amount of quinine the mixture was supposed to contain, e.g., 10 grains to the ounce. A precipitate forms which will settle and the two tubes can be compared in half-an-hour's time. Any gross deficiency will be obvious.

Tanret-Mayer test for quinine in urine

The reagent is made as follows:—Add a solution of 1.45 grammes of mercuric chloride in 80 c.cm. of undistilled water to a solution of 5 grammes of potassium iodide in 20 c.cm. of distilled water, agitating the solution all the time. To test the urine, first boil and then filter it, then add a few drops of reagent to

Fig. 2.—Monthly incidence of malarial attacks.

Number of subjects.

A = Controls	91 ± 14
B = Quinine 0.4 gramme daily.	91 ± 17
C = Atebrin 0.4 gramme weekly.	103 ± 12

the dishonesty or carelessness of the dispenser or of the manufacturer; many instances have been reported in which serious consequences have resulted.

(2) Faulty preparation of the tablets, that is, they may be insoluble through the presence of too much amorphous alkaloids, or coated with some insoluble substance.

(3) Vomiting of the mixture, or tablet.

(4) Failure of absorption by the gastric mucosa.

(5) Deception by the patient himself, or herself, on account of prejudice (pregnant woman) or malingering.

The methods that can be recommended to circumvent some of these occurrences are to test the stock mixtures by means of the simple technique suggested by Sir John Megaw, and to test the urine of the patient by the Tanret-Mayer test for the presence of quinine.

5 c.cm. of the urine: an immediate precipitate forms if the alkaloid, quinine, is being excreted in the urine.

Parenteral therapy

It is not proposed to discuss here the vexed question of intramuscular *versus* intravenous therapy and for the moment they will be referred to together as *par-enteral* (=para=besides; *enteron*=intestine) therapy.

The points for and against this method of administration may be considered under the following headings:—

Necessity.—In certain circumstances parenteral therapy is essential, as for example in unconscious cerebral cases and in cases where there is persistent vomiting.

Advantages.—The main advantages are that one gives the injection oneself, and is therefore certain that it has been taken, and further that it has been absorbed.

Dangers.—These are not very great if sufficient care is taken. Scrupulous asepsis is required in the case of intramuscular injection, or abscess and even tetanus may follow. Secondly, great care must be taken to avoid large nerves, or neuritis or paralysis may be caused. Many instances of severe and permanent damage following careless administration have been recorded and illustrated in the literature.

In the case of intravenous therapy the injections must be given slowly and the drug well diluted, or syncope and collapse may occur.

Preparations and dosage. Intravenous.—Ten grains of quinine hydrobromide in 20 c.cm. of normal saline; repeated again later in the day; or

atebrin musonate 0.125 g. (=0.1 g. atebrian hydrochloride) in 3 c.cm. of distilled water, given three times in the day.

Intramuscular.—Ten grains of quinine hydrobromide or bihydrochloride in 4 c.cm. of saline, given into the gluteus maximus, the vastus externus, the muscles at the angle of the scapula, or the deltoid;

or
atebrin musonate 0.375 g. (=0.3 of atebrian hydrochloride) in 9 c.cm. of distilled water, into one of these muscles.

However, even when parenteral therapy is indicated, it is seldom necessary to continue it beyond the first day: after this oral therapy can usually be instituted.

Before passing on to the next heading, mention must be made of a recommendation of the Health Committee of the League of Nations, which has been severely criticized, but with which the writer is in part agreement. They recommend that in the *initial* attack of malaria the patient should be allowed to remain untreated for a few paroxysms in order that he may work up his natural immunity before he is given any anti-malarial drug.

This suggestion is based on reliable experimental evidence and it is no doubt absolutely sound advice, in theory, but in practice it is seldom possible to do this, as in most cases the patient's only desire is to be cured of the immediate attack, and if one insisted he would simply call in another doctor. It is, in any case, only advocated in benign tertian infections.

(iv) *Treatment to prevent relapses.*—The big-stick methods which were at one time popular, large daily doses of quinine over long periods, have quite gone out of fashion. The average case of malignant tertian infection will not relapse after the ordinary curative dose of cinchona, quinine or atebrian, but as relapse may be serious a second course after an interval of 7 to 10 days is usually advisable; the same remark applies to quartan infections. In the case of benign tertian infections the relapse rate after quinine alone is usually high (70 per cent) and some special measures should certainly be adopted.

Following the line of thought started by Acton who showed that quinine acted best in an alkaline substratum, Sinton advocated the following routine procedure in the treatment of relapsing benign tertian malaria.

The two mixtures he used were—

Mixture A

R	Sodii bicarbonatis	gr. lx
	Sodii citratis	gr. xl
	Aquam ad	ʒi

Mixture B

R	Quininae sulphatis	gr. x
	Acidi citratis	gr. xx
	(or acidi sulph. dil)	m. xxx)
	Aquam ad	ʒi

Course

Give calomel in divided doses, i.e., 6 quarter-grain doses at half-hour intervals at night, and magnesium sulphate at 6 o'clock in the morning, ʒss to ʒi: at 7-30, 9-30 and 11-30 give one dose of mixture A followed by a dose of mixture B at 12 o'clock; at 6 o'clock give a dose of mixture A, followed half an hour later by a dose of mixture B.

From the 2nd to 5th days inclusive give three times during the day a dose of mixture A, followed half an hour later by a dose of mixture B.

On the 6th and 7th days give a dose of mixture A, followed half an hour later by one of mixture B, twice during the day.

This makes a total dose of 180 grammes of quinine. Totaquina may be substituted for quinine without detriment to the treatment and where economy is to be considered this should always be done.

Quinine plus plasmochin

A very marked further reduction in the relapse rate in benign tertian malaria can be obtained by the addition of plasmochin to the quinine. The following dosages are recommended; the results obtained with each of these courses are about the same, but in either case the patients should be kept under observation for signs of intolerance to plasmochin.

Plasmochin 0.02 gramme \times 2 + 20 grains of quinine, or

Plasmochin 0.01 gramme \times 3 + 30 grains of quinine

—daily for seven days.

Atebrin and atebrian plus plasmochin

Better results have been obtained with atebrian alone than with quinine alone, but, even with atebrian, plasmochin can be added with advantage in benign tertian infections.

Atebrin 0.1 g. thrice daily + plasmochin 0.02 g. once a day for 5 days—given together or separately,

Atebrin 0.1 g. + plasmochin 0.0033, combined in one tablet, thrice daily for 5 days.

Many workers believe that the toxic symptoms produced by atebrian are more likely to

occur when plasmochin is given with it; though this point has not been finally settled it is again best to keep the patients under observation when the combined dosage is given.

(v) *Gametocyte destruction in the cause of general prophylaxis.*—This does not in any way help the patient, as gametocytes can never again become asexual forms as long as they remain in the blood, but if they are taken up by a mosquito they develop and the infection may be transmitted to others. It is therefore only in the interests of *general prophylaxis* that attempts should be made to destroy gametocytes.

It is in this capacity that plasmochin is unique. No other drug that we know will destroy the gametocytes of malignant tertian, but this can be effected by a very small dose of plasmochin, 0.01 gramme, twice a day for three days, given for the last three days with the quinine or atebirin, or after the course has been finished.

Mass treatment with plasmochin is a suitable prophylactic measure for isolated communities, but it is essential that every single member of the community, not excluding infants, should be treated.

A comprehensive course

Now we have considered treatment of malaria under the five headings separately, but in most circumstances you will wish to achieve more than one of these aims; in fact, except for the first aim which I have said cannot be achieved with any drug we have at our disposal, you will often wish to achieve all of them. That is to say, you will want to treat the clinical attack, you will want to ensure that the condition does not relapse, that the patient does not get reinfected, and finally that he is not a source of infection to others. For this, I can recommend a routine course as follows:—

Atebrin 0.1 gramme (or $1\frac{1}{2}$ grains) three times a day with plasmochin 0.02 gramme (or $\frac{1}{3}$ grain) once a day, for five days, followed by 0.2 g. atebirin in a single dose on two consecutive days each week.

Or, if the cinchona alkaloids are preferred to atebirin, totaquina gr. 10 three times a day and plasmochin 0.02 gramme once a day, for seven days, followed by totaquina gr. 6 daily, as long as prophylaxis is to be maintained.

Toxic effects

Although toxic effects do occasionally follow atebirin administration, there is a considerable amount of misapprehension on the subject and I feel that a few words on the toxicity of atebirin will be appropriate here.

Almost without exception all drugs that are active are toxic. Toxicity must therefore be considered relatively—the dose administered and the person to whom it is administered. There is strong evidence that atebirin given in the

ordinary therapeutic doses is not toxic to the ordinary individual—occasionally a patient who has some idiosyncrasy to the drug will show special symptoms.

The incidence of toxic symptoms.—This personal idiosyncrasy is our experience with all drugs, but the practitioner naturally wants to know how often these susceptible individuals are likely to crop up in his practice.

I can quote a few figures from recent experience in India and Malaya.

Williams and Bhattacharyya (1935) reporting mass treatment in Assam gave the following figures:—

234 tea-garden coolies (1 gramme of atebirin in five days)—8 cases of mild ill-effects, including 3 of yellow discoloration, 3 of giddiness, 1 of slight abdominal pains and 1 of anorexia.

Newman and Chalam (1935) reported as follows:—

258 railway employees (atebrin 1.5 g., plasmochin 0.15 g. given separately over a period of 5 days)—slight yellow discoloration in 5, gastric symptoms in 7, and more severe gastric pains in 3.

They had a higher incidence of ill-effects when the drugs were given together.

In a group of coolies in Malaya, Green (1934) reported the following results:—

613 working coolies (1.5 g. atebirin in 5 days)—no symptoms reported.

117 hospital cases (2.1 g. atebirin in 7 days)—10 per cent had slight symptoms.

20 special hospital cases (2.8 g. atebirin in 7 days)—35 per cent had symptoms, some severe.

Wallace (1936) reported the mass treatment of 3,000 Malayan coolies (1.5 g. atebirin in 5 days) with 3 per cent mild and transient symptoms and no psychoses.

He also referred to three groups of mass-treated cases (atebrin 1.5 g. + plasmochin 0.14 g. in 7 days) in which there were 1 per cent, 1 per cent, and 2.3 per cent mild symptoms, respectively, in the different groups.

It will be seen that with an increase in dosage there is an increase in the incidence of by-effects. Nevertheless, if the practitioner keeps to the ordinary dosage, which is an efficient dosage, he will seldom in his whole experience meet with anything but the mildest by-effects and these should not deter him from using a valuable drug.

The actual and reputed by-effects can be classified as follows:—

(i) *Due to a misconception*—e.g., yellow colour mistaken for jaundice.

(ii) *Symptoms really due to malaria itself*—e.g., gastro-intestinal or cerebral disturbances, hæmoglobinuria.

(iii) *Symptoms following overdosage*, as noted below (iv) and (v) in—

(a) patients who have undertaken treatment themselves,

(b) patients who have been first treated by a doctor and then continued treatment themselves, and

(c) patients whose doctors have wrongly advised them through ignorance.

(iv) *Mild by-effects which cannot harm the patient but about which the doctor should warn him—e.g., (a) yellow discoloration—suggesting that the drug is not being properly excreted; this should also act as a warning signal, and*

(b) a 'knocked-out' feeling (general lassitude) due to reduction in hæmoglobin which is dependent on destruction of parasitized red cells (it does not occur in the uninfected person receiving atabrin).

(v) *Personal idiosyncrasy following ordinary dosage—e.g., gastric pains, headaches, giddiness, anorexia, hæmoglobinuria, epileptiform fits, and psychoses.*

Hæmoglobinuria is more usually associated with plasmochin administration.

Epileptiform fits have been reported—the consequence was not serious and the evidence that they were actually caused by the drug was not complete. A few cases of temporary psychosis have been reported from Malaya where an enormous number of people have been treated by the drug.

(vi) It is known that plasmochin in large doses will give rise to symptoms (e.g., cyanosis, syncope, hæmoglobinuria, gastric pains); it is suggested that the addition of plasmochin will increase the toxicity of atabrin. This is still doubtful but some workers advocate the separate administration of these two drugs.

I will conclude by repeating that the average practitioner will seldom encounter any serious ill-effects after atabrin administration if he follows the orthodox dosage. At the School of Tropical Medicine, though we have had patients who have come into hospital for treatment on account of suggestive symptoms following the administration of both atabrin and plasmochin, we have treated many hundreds of patients with atabrin during the last six years and in none of these have any serious symptoms followed.

Medical News

KING GEORGE THANKSGIVING (ANTI-TUBERCULOSIS) FUND.

SUMMARY OF TUBERCULOSIS NEWS FOR JANUARY 1938.

Post-graduate course in tuberculosis.—The sixth post-graduate course, organized under the auspices of the Fund, took place at the All-India Institute of Hygiene, under the chairmanship of Col. P. S. Mills, Surgeon-General with the Government of Bengal and Chairman of the Bengal Provincial Anti-Tuberculosis Sub-Committee. Thirty doctors from all over India attended this course.

Dr. Sikand, Organizing Secretary of the Fund, in welcoming the candidates, said that one of the important items in the medical control of tuberculosis is the training of physicians, and, as such, formed one of the activities of the Fund. The object of the course was to train workers who will return to their areas in a real missionary spirit and help to organize anti-tuberculosis measures.

Col. Mills in his presidential address referred to tuberculosis as a symptom of a very much wider disease, i.e., the economic disease. It was a symptom among many others of world conditions resulting in a state of affairs by which human beings were living in bad physical surroundings. Enormous numbers of people were badly housed, had insufficient food and a quality of food that was not suited to equip them in the great fight against parasites, which were lying in wait to attack mankind on this earth, where life is characterized by universal parasitism. In the appeal under the King-Emperor's Anti-Tuberculosis Fund a great effort has recently been launched. It was devoutly to be hoped that those who had come to attend the course would, in their turn, do all in their power in the future to help that effort.

Sir Upendra Nath Brahmachari in his opening address, after quoting figures to show that, while tuberculosis was declining in other countries, it was increasing in India, pointed out the danger of spread to the villages as a result of urbanization and industrialization. He stressed on many points that were essential in the campaign against tuberculosis.

Anti-Tuberculosis Work in Bombay Presidency.—Though the city of Bombay had quite a comprehensive anti-tuberculosis scheme for several years past, yet the work outside Bombay had not made much headway till a new orientation was given to it by a committee which was reorganized in 1936 as a sub-committee of the Bombay Red Cross Society under the chairmanship of the surgeon-general.

The committee concentrated its attention on the work of tuberculosis clinics, six of which, attached to the civil hospitals at Ahmedabad, Surat, Poona, Sholapur, Nasik and Belgaum, were opened in April 1937. Each clinic is under the charge of a qualified medical officer, assisted by a duly registered nurse, both of whom have had a month's training in tuberculosis institutions.

Out of 2,441 new cases examined, 597 new cases of tuberculosis were discovered. The health visitors paid 6,400 domiciliary visits and arranged for the examination of 2,054 contacts.

The annual cost estimated on six clinics is about Rs. 14,680, of which half the expenditure of Rs. 8,280 on nurses is borne by the Bombay Provincial Branch of the Red Cross Society, and the other half by the Bombay Government. The annual grant of Rs. 3,000 paid by the King George Thanksgiving Fund is received by the Society.

Proposals have been submitted to the Bombay Government for affording facilities for three microscopic examinations of sputa at government hospitals and laboratories.

The civil surgeons have been requested to arrange short instructive courses of lectures and clinical demonstrations in consultation with the medical officers in charge of clinics and local medical associations, where they exist.

TENTH INTERNATIONAL CONGRESS OF DERMATOLOGY AND SYPHILOLOGY.

The Tenth International Congress of Dermatology and Syphilology will be held in New York City, U. S. A., in September 1940. Dr. Oliver S. Ormsby is President and Dr. Paul A. O'Leary, Mayo Clinic, Rochester, Minnesota, U. S. A., is the Executive Secretary.

REPORT OF THE FIRST BOMBAY PROVINCIAL CONFERENCE OF THE ALL-INDIA MEDICAL LICENTIATES' ASSOCIATION.

The opening session of the conference commenced at 2-30 p.m. (S. T.) on Saturday, the 18th December 1937, in the Dhanraj Hall (main lecture hall) of the National Medical College, Bombay. Amongst the distinguished guests were: Major-General H. C. Buckley, Surgeon-General with the Government of Bombay, Major Chopra, P. A. to the S. G. with the Government of Bombay, Lieut.-Colonel Vazifdar, President, College of Physicians and Surgeons of Bombay, Dr. D. H. Dudha, Principal, National Medical College, Bombay, Dr. H. V. Tilak, C. M. O., Nair Hospital, Bombay, Dr. V. G. Rele, Ex-Principal of the National Medical College, Bombay, Rao Bahadur Dr. R. V. Mone, Civil Surgeon, Thana, Dr. A. V. Baligra, Hony. Surgeon, K. E. M. Hospital, Bombay, and others.

Major-General Buckley in his inaugural speech said that the conference would consider many important questions. He asked the conference to give deep consideration to the problem of medical relief in rural areas. Another problem the conference would have to consider was that of medical education. In another province he had preached in and out of season that the day of the medical school was past. There should, he said, be one standard of education, the four-year course should be raised to a five-year course, and the education should be of the university standard. He further observed that the Medical Council should be the most important body in dealing with the affairs of the profession in the province and asked the conference to think very clearly in defining its attitude to the Council, for the prestige of that body should be maintained and no attempt should be made to turn it into a mere debating society.

Dr. U. Shesha Rao, the Provincial Secretary, then read his report for the year. In his report he pointed out the various advantages that would accrue if the licentiates were all to join under the banner of the All-India Medical Licentiates' Association and concluded it by exhorting the Licentiates, one and all, to immediately join the Association if they have not already done so and thus strengthen the hands of the Association in getting all their legitimate grievances redressed.

Presidential Address: Dr. Joseph Benjamin in his presidential address pointed out that the interests of the Licentiates were not safeguarded in the Bombay Medical Council as they should be owing to the poor representation given to the Licentiates therein. He said that a deputation should wait on the Hon'ble the Minister of Health to request him to amend the Bombay Medical Act on a democratic basis and hoped that the Hon'ble Dr. Gilder would take up the cause of the Licentiates in the Bombay Legislative Assembly and introduce a bill for the purpose. Dr. Benjamin appealed to the members of the Indian Medical Council as well as the members of the Central Assembly to move an amendment to the Indian Medical Act so as to include the Indian Medical Licentiates in it.

The President said that it was high time that Licentiates are taken on the Board of Management of the College of Physicians and Surgeons, Bombay, so that they could watch the interests of their class. Licentiates earnestly desired that the door to appear for competitive examinations for all the medical services in India should be opened to them also.

The remaining days of the conference were devoted to the reading and discussion of papers, and visits to various commercial undertakings concerned with the manufacture of drugs and other medical supplies.

Resolutions.—This conference is of opinion that the L.C.P.S. Course should be abolished from 1938 and requests the Government of Bombay and the Bombay Medical Council to take the necessary steps in the matter.

Resolved that this conference requests the Bombay Government to amend the Bombay Medical Act VI of 1912 as follows:—An elected president; an elected vice-president; six seats for the graduates and six seats for the Licentiates and others in the register and three to be nominated by the Government.

Resolved that the Medical Licentiates be given equal representation on the Board of the College of Physicians and Surgeons so long as it exists.

Resolved that the Bombay University be requested to kindly permit the L.C.P.S.'s (Bom.) to appear for the M.B., B.S. Examination after attending the course for two years at a medical college without insisting for preliminary educational standard.

Resolved that the Bombay Medical Council be urged to throw open the meetings of its Executive Committee to the registered medical practitioners and the medical and lay press representatives, except during the deliberations of penal cases.

Resolved that the Bombay Medical Council be requested to effect the necessary changes in the present code of medical ethics only after duly consulting the medical men on their register, medical associations and the medical press.

Resolved that the Surgeon-General with the Government of Bombay be requested to give effect to the Government of India resolution No. 9211, dated 14th November, 1914, about the promotion of deserving and experienced men in the S. M. S. to the B. M. S. Cadre.

This conference views with deep concern the appointment of graduates in the cadre of S. M. S. Officers, which has been an encroachment upon the rights of these deserving men who enjoyed the privilege till now, and requests the Government to stop further enlistment of graduates into the S. M. S. Cadre.

Resolved unanimously that the Bombay Government be requested to give honorary appointments to Licentiates of approved merit and experience in civil hospitals.

Resolved that the Government of India be requested to amend as early as possible the Indian Medical Council Act of 1933, so as to include Indian Medical Licentiates within its scope and requests the present members of the Indian Medical Council as well as members of the Central Legislative Assembly to take immediate steps to remove the injustice which has been done to the Indian Medical Licentiates by their exclusion from the scope of the Act.

Resolved unanimously that the Bombay Government be requested to grant study leave to the desiring members of the Sub-Medical Service class under the same conditions as granted to men in the higher medical services.

In view of the onerous and hard duties which the Medical Licentiates have to perform in various capacities, the Bombay Government be requested to continue the same scale of pay as it is existing at present.

This conference notes with deep concern the recent Government resolution No. 1714/33, dated 16th November, 1937, excluding Bombay Medical Service, Class II Officers, who are not graduates from the membership of Medical Boards constituted for the purpose of commutation of pension and therefore requests the Government to remove this humiliating restriction in the case of the non-graduates, Bombay Medical Service, Class II Officers, and to allow them all the rights and privileges of that service.

This conference recommends to the Board of College of Physicians and Surgeons of Bombay to appoint as examiners only those who have been in the teaching line.

Resolved that the Government and the local authorities be requested to allow the use of the courtesy title of 'Dr.' in the official correspondence to all registered Medical Practitioners under them.

This conference is of opinion that none but registered Medical Practitioners should prescribe poisonous drugs of the British Pharmacopœia or its preparations and that it should be made illegal for any chemist to dispense a prescription containing such drugs or prescriptions unless signed by a registered Medical Practitioner.

Resolved that the Dangerous Drugs Act 2 of April 1936 be repealed so as not to affect the registered Medical Practitioners.

This conference requests the Bombay Government to enact legislation to prevent the practice of Western (allopathic) system of medicine by those who do not possess registrable qualifications and also to make it illegal to use the title of 'Doctor' by any one who does not possess registrable medical qualification.

Resolved unanimously that the Surgeon-General with the Government of Bombay be requested that the present orders debarring failed students in the final L. C. P. S. Examination to re-appear in the examination

after five failures be withdrawn as early as possible in view of the hardships undergone by the medical students and having no other line open to them after passing two examinations and studying the medical schools for a period of four and a half years or more.

Resolved unanimously that the Bombay Government be urged that medical certificates granted by registered Medical Practitioners be accepted by the officers concerned without the same being countersigned by the Civil Surgeons or the Administrative Medical Officers.

INDIAN MEDICAL COUNCIL.

Under section 3(1)(a) of the Indian Medical Council Act, 1933, the Governor is pleased to nominate Colonel P. S. Mills, C.I.E., I.M.S., Surgeon-General with the Government of Bengal, to be a member of the Medical Council of India in the place of Major-General D. P. Goil, I.M.S., resigned.

Colonel G. G. Jolly, I.M.S., nominated as a Member of the Medical Council of India, from the Punjab vice Colonel C. H. Reinhold, I.M.S., resigned.

Study of the Therapeutics and Prophylaxis of Malaria by Synthetic Drugs as Compared with Quinine

(Extract from the Fourth General Report of the Malaria Commission of the Health Organization of the League of Nations, 1938)

1. ACTION OF QUININE AND OF SYNTHETIC PRODUCTS ON THE DIFFERENT MANIFESTATIONS OF MALARIAL INFECTION

(a) Quinine

(1) Action on the trophozoites in primary infections. A minimum daily dose of 0.50 gm. of quinine hydrochloride sometimes suffices to cause a temporary disappearance of the trophozoites of *P. vivax*; but a mean daily dosage of 1 gm. for five to seven days is often necessary to cause the trophozoites to disappear (on an average on the third day) and not to make their reappearance in the peripheral blood until after a latent period of varying length, in the course of the first relapse. In quartan (*P. malaria*) the same effects are usually obtained. In infections with *P. falciparum*, the average effective daily dose should be fixed at about 1.30 gm. to produce analogous results. In some countries, it is even necessary to use 2 gm. in order to obtain a rapid effect upon the clinical attack and on the parasites. With the usual dose of 1 gm. the trophozoites generally disappear one day later, on the average, than in the case of *P. vivax*; sometimes their resistance continues even longer.

(2) Action on the gametocytes of *P. vivax* and *P. malaria*. Quinine, in the doses indicated, exercises its parasitidal activities on the young forms of *P. vivax* and *P. malaria* capable of producing gametocytes, and also on fully-developed gametocytes. On the fully-developed gametocytes of *P. falciparum*, quinine has only a very slight action; but it also impedes the formation of the pre-gametocytes of this species. It may thus be regarded as directly schizonticidal and indirectly gametocidal in the case of *P. falciparum*.

(3) On the acute clinical symptoms of primary infection, quinine, in the indicated doses, has a definite action from the third day onwards (second paroxysms of fever) in benign tertian; its action is less reliable or less rapid, according to the strain of *P. falciparum* concerned, on attacks of malignant tertian, which often continue until the fifth dose (third or fourth paroxysm).

(4) On the frequency of relapses in general, quinine has a clearly marked effect which is, however, influenced by individual factors and by the strain of parasite.

The treatment of primary *P. vivax* or *P. malaria* infections with quinine in the usual doses (1 gm. daily) is followed by relapses in a proportion of individuals which may be as high as 50 per cent.

(5) The action of quinine on splenomegaly, when suitable treatment is applied in each attack, has proved to be of real efficacy in endemic regions, especially among children. It is but transient, however, if the community concerned is subject to a high proportion of relapses or is exposed to frequent reinfections.

(6) Quinine treatment with the usual doses does not affect the patient's general condition adversely and generally has no depressive or toxic effect, if the period of administration is limited to the strictly necessary number of days. In such a case, there is no good reason for thinking that this treatment hinders the processes of immunization, but ill effects may occur when treatment is unnecessarily protracted.

(b) Atebrin

(1) Action on the trophozoites. Atebrin in daily doses of 0.30 gm. (for adults) has a slightly more rapid action on *P. vivax* trophozoites than quinine in the usual dose of 1 gm. The trophozoites disappear on an average after the third dose, and in some cases even after the second. This parasitidal action appears to continue for a longer period, in that the phase of latency of the disease (absence of clinical symptoms) is established more certainly and lasts somewhat longer after the end of treatment with atebrin than with quinine. On the trophozoites of *P. malaria*, the action of atebrin can be said to be of the same nature. On the trophozoites of *P. falciparum*, atebrin is equally in advance of quinine in certain cases; but the differences between the strains of parasite prevent the drawing of uniform conclusions. The trophozoites of *P. falciparum* disappear from the peripheral blood after the fourth dose of atebrin in 90 per cent of cases.

(2) The action of atebrin on the gametocytes is of a similar nature to that of quinine; it has no effect, from the point of view of devitalization, on the gametocytes of *P. falciparum*. But the action on gametocytes already present in the blood is perhaps slightly more marked than that of quinine, particularly as regards the gametocytes of *P. vivax* and *P. malaria*.

(3) The action on the clinical symptoms of an acute attack is very marked, both in benign tertian and in malignant tertian. In some endemic regions, where there may possibly be special strains of *P. falciparum*, the therapeutic action of atebrin is even more energetic on malignant tertian than on benign tertian.

But, in other cases, the contrary seems to be true. This is why some practitioners and malariologists in tropical countries prefer to use quinine during the first days of the acute attack and to continue with atebirin thereafter. In benign tertian the fever nearly always falls after the first three therapeutic doses of atebirin—that is to say by the second attack. In malignant tertian the fever falls almost invariably by the third attack.

(4) *The action of atebirin on relapses is slightly more effective than that of quinine, especially in the case of benign tertian and of certain strains of malignant tertian.*

(5) *The spleen rate in communities treated with atebirin seems to decrease somewhat more slowly than in communities treated with quinine, but the effects of the drug continue to be felt for a longer time during the observation period after the end of the treatment, the decrease in the percentage of enlarged spleens continues longer, and the return of the splenic index figures to their former high level occurs a little later.*

(6) *The action of atebirin on the general condition of patients seems to be determined by factors which, after this form of treatment, are still not entirely known—that is to say, by the action of the drug on the organic defences in general and on the processes of immunization. The yellow coloration of the skin produced by atebirin is a disadvantage, especially during prolonged prophylactic treatments.*

(e) *Plasmoquine*

(1) *Action on the trophozoites.*—The action of plasmoquine on the trophozoites of *P. falciparum* is almost nil. It acts to some extent on the trophozoites of *P. vivax*, and especially on those of *P. malariae*. With small non-toxic doses of plasmoquine associated with the usual doses of quinine or atebirin, better results are sometimes obtained on the trophozoites of *P. vivax* and even of *P. falciparum*.

(2) *Plasmoquine acts upon the gametocytes of the three species, but especially on those of P. falciparum, which are practically unaffected either by quinine or by atebirin.* In minimum doses of 0.12 grm., plasmoquine devitalizes the gametocytes of *P. falciparum* and at the same time diminishes their numbers.

(3) There is no advantage in using plasmoquine alone for the treatment of the clinical symptoms of an acute attack in any of the forms of malarial infection.

(4) *Plasmoquine has a definite effect upon the frequency of relapses of benign tertian or quartan.* In association with quinine or atebirin, or administered after either of these two drugs, it is to a marked degree effective in preventing relapses in benign tertian (except perhaps in the case of a few particular strains) and quartan, and appears similarly to reduce the frequency of malignant tertian relapses.

(5) We do not possess sufficient data to assess the action of plasmoquine alone, used either therapeutically or prophylactically, upon the state of the spleens in malarial communities, for it is nearly always administered together with other drugs.

(6) The small doses of plasmoquine (0.02 grm. for example) that are now being used seem to have no serious depressing effect on the general state of the patient. That the prolonged use of plasmoquine may exert some influence on the neoformation of hæmoglobin must not be overlooked.

(d) *Quinine-atebirin, quinine-plasmoquine and atebirin-plasmoquine combinations*

(1) The few experimental observations that have been published give no indication that there is any advantage in combining quinine and atebirin together for purposes of treatment.* Further clinical research is required in order to determine the effects of these two drugs, when administered one after the other (usually quinine first and atebirin afterwards), in the

treatment of acute attacks of certain kinds of infection, especially *P. falciparum*.

(2) The combined use of quinine with plasmoquine produces less frequent and less intense toxic symptoms than that of atebirin with plasmoquine. The association properly so called (that is to say, the simultaneous use) of quinine and plasmoquine (for example, up to 0.02 grm. or even 0.03 grm. of plasmoquine daily for short treatments) therefore does not involve any particular contra-indications. Certain authors recommend however that, whenever possible, the two drugs be administered consecutively. For the treatment of adult groups under observation (soldiers, workers) there is, however, no serious disadvantage to be feared from the simultaneous use of quinine and plasmoquine, which moreover shortens the duration of treatment.

The association of quinine with plasmoquine represents one of the most efficacious methods of treating benign tertian and quartan malaria. Treatment with average doses (1 grm. to 1.30 grm.) of quinine plus plasmoquine (even only 0.02 grm. to 0.03 grm. twice a week) greatly reduces (perhaps more than any other method) the number of relapses in benign tertian (except, as already indicated, in the case of certain strains) and in some cases also in malignant tertian.

(3) *The simultaneous administration of atebirin and plasmoquine appears to aggravate the toxicity of each.* It is not to be advised, though it is understood to have been used without ill effects in certain communities of adult men. It should in any case not be adopted without medical supervision. Consecutive treatment with atebirin first and then with plasmoquine in suitable doses (0.30 grm. atebirin daily for five or seven days followed by 0.02 grm. plasmoquine daily for five days) has no appreciable influence either in reducing the proportion of trophozoites in the blood or on the clinical manifestations. Like the quinine plus plasmoquine treatment, that method has, however, the advantage of decreasing and devitalizing the gametocytes, especially those of *P. falciparum*. Moreover, from the clinical point of view, it diminishes substantially the number of relapses, both in malignant tertian and, more especially, in benign tertian and quartan.

2. PRACTICAL SUGGESTIONS FOR TREATMENT AND PROPHYLAXIS

Without presuming to lay down hard and fast rules, and while avoiding any interference with either the personal freedom of the doctor, who has to take the responsibility for the treatment of each case, or the initiative of the malariologists, who have to judge the different circumstances of the local epidemiology in the field, the commission believes that it is in a position to give certain indications. Account should however first be taken of the following points, on which reservations have been made in the previous pages, with respect not only to the individual treatment of patients, but generally also to the application of any therapeutic procedure: (1) The varying reactions of the different parasite strains of the same species and of patients to the drugs; (2) the special indications applicable to the parenteral administration of drugs; (3) the drawbacks of the synthetic products (yellow coloration of the skin by atebirin, toxicity of plasmoquine).

(a) *Individual treatment of patients*

It is always desirable that the doctor should be in a position to diagnose malaria and to determine the species of parasite concerned, by microscopic examination of the blood.

In ordinary cases of *P. vivax* (benign tertian) infections, it is almost immaterial whether quinine or atebirin is employed for treatment of the attack. Plasmoquine, associated with quinine or atebirin, or administered after these drugs, has no appreciably useful effect on the attacks but seems to reduce the frequency of subsequent relapses.

The association of plasmoquine with quinine, or its administration after atebirin, is useful in *P. falciparum* infections, on account of its action on gametocytes and relapses.

*Prof. Rodhain, in a private communication, states that he has recently obtained beneficial effects by this method.

(b) *Treatment in the field*

Atebrin, when used for collective treatment in daily doses of 0.30 gm. (for adults) for five to seven days, acts in the same way as quinine in daily doses of 1 gm. to 1.30 gm. for five to seven days or more. There is no reason save financial considerations, why either quinine or atebrin should be preferred. The manner in which collective treatment is conducted will depend upon the intensity of the endemicity, which is itself the resultant of a series of factors; the virulence of the strains, the sensitiveness of the strains to the various drugs, the susceptibility of various population groups, etc.

Collective treatment with quinine or atebrin may usefully be accompanied or followed by plasmoquine treatment, in order to diminish the number of gametocytes and the risk of relapses. The choice of the basic drug for collective treatment should be left to the public administrations or malaria-logical organizations which undertake or control such treatment, and will be guided by local and economic considerations as well as by the preferences of the medical profession and of the population. It should, however, be remembered that the choice of drug, as well as dosage and duration of therapeutic administration, should, so far as possible, be directed towards the achievement of the real aim of mass treatment. This aim is: (1) to secure the largest number of complete cures in case of malaria (*intensive treatment of patients*); (2) to reduce to a minimum the risk of anopheline infection, either by direct action upon the gametocytes, or by indirect action on the parasites generally, thereby effecting an eventual reduction in the number of carriers of sexual forms (*gametocyte therapy*). It would therefore be wise not to rely on plasmoquine alone for this second purpose. These considerations also apply to the choice of the basic drug and the manner of its administration to the community, either directly associated with or followed by plasmoquine.

There are, however, large malarial areas, especially in the tropics, where such mass treatment is impossible of practical application for various reasons, often financial. Under such conditions, it is desirable to provide adequate and easily available treatment for the clinical manifestations of the disease, so that the morbidity, the mortality and the physical incapacitation of the afflicted individuals are diminished. Such treatment has very often to be placed in the hands of laymen for distribution, and little or no direct medical supervision is possible. In these circumstances, the cinchona alkaloids appear to be the more suitable drugs.

(c) *Mass drug prophylaxis*

Mass drug prophylaxis has a twofold purpose: (1) to protect the population undergoing prophylactic treatment from the clinical manifestations of endemic malaria, in order that its working capacity and comparative standard of health may be safeguarded without injury to its premunization, even in areas in which it is exposed to repeated reinfection; (2) to reduce, in due course, the sources from which the local mosquito population may be infected. Unless applied to disciplined communities under stringent supervision, is capable as yet of attaining these two objects. Special stress should be laid upon the desirability and, at the same time, the difficulty of promoting the immunization process in the population, which depends precisely upon the degree of tolerance to infection and upon repeated reinfection. At the same time one wishes to avoid the risks attendant upon the presence and persistence of such latent infections in the community. Experience has shown, at all events, that very useful results can be obtained during the whole of the malaria transmission season, and even for a few weeks longer. This is also true of bi-weekly doses of atebrin (0.20 gm. = 0.40 gm. per week) administered in certain conditions. With the latter method (bi-weekly atebrin), which has given encouraging results, further

trials would be desirable. The daily dose of 0.05 gm. of atebrin recommended for prophylactic purposes has proved inadequate. The harmlessness of quinine makes it a suitable drug for administration by subordinate personnel without constant medical supervision, whereas such supervision is essential in the case of atebrin. Plasmoquine is otherwise than under direct medical control. Its use in mass prophylaxis would be justifiable only if it were administered to a disciplined population, which should be kept under constant medical care. It is useful more especially for the purpose of ultimately reducing the number of gametocyte carriers and arresting the transmission of infection to the anopheles. Plasmoquine is certainly the gametocidal agent *par excellence*, especially where *P. falciparum* is concerned. But both quinine and atebrin also exercise in the latter case a gametocidal action (mainly indirect) by destroying the sexual forms in process of development.

The real efficiency of such methods in the field is, moreover, largely dependent upon a highly important epidemiological factor: namely the children. The proportion of gametocyte carriers is much higher among children than among adults, given the same environmental conditions (village, house, family) in respect of endemicity and anophelism. Children, on the other hand, are more difficult to subject to regular treatment, and finally, as already pointed out, the doses and form of administration of atebrin and plasmoquine to children cannot yet be regarded as finally settled.

(d) *Drug eradication*

Experience has so far shown that the eradication of malaria from a locality by the curative and prophylactic treatment, with the drugs at present available, is practically impossible. To begin with, it is impossible to reach, in sufficient time, all the inhabitants of an area, or even of a small village. Moreover, while curative and prophylactic treatment may greatly diminish the morbidity yet it cannot suppress the parasites in all the carriers.

In this report, the commission has not considered the question of expenditure entailed by treatment and prophylaxis campaigns, which depends upon the price of drugs and the cost of staff. It would, however, emphasize the great importance of this problem—which will probably be studied in detail by the Malaria Commission in the near future—in connection with the choice of drugs to be used for curative or prophylactic mass treatment. Among those drugs, quinine still ranks first in current practice, by reason of its clinical effectiveness and almost complete absence of toxicity, coupled with the widespread knowledge of its use and dosage. As regards the synthetic products, which have only been used in therapeutics for ten years, the commission hopes that it has discharged the duty which devolved upon it by giving in this Fourth General Report an account of the present state of our knowledge regarding the possible use of atebrin and plasmoquine in treatment and prophylaxis of malaria. In certain circumstances, as has been shown above, these drugs—representing a notable scientific advance—possess a very special value.

Sulphanilamide in the Treatment of Gonorrhœa

By HAROLD ORR, O.R.E., M.D., D.P.H., F.R.C.P. (C.)
(Abstracted from the *Canadian Medical Association Journal*, Vol. XXXVII, No. 4, October, 1937, p. 364)

THE MODE OF ACTION OF SULPHANILAMIDE
LONG and BLISS have shown that a 1:10,000 concentration of para-amino-benzene-sulphonamide in serum broth markedly inhibited the growth of alpha hæmolytic streptococci, gamma streptococci, pneumococcus types I and II, several varieties of *Neisseria* from the

throat, *M. tetragenus*, *H. influenza* and *H. hæmolyticus*. The growth of *S. aureus*, *B. typhosus*, *B. para-typhosus* A, *B. para-typhosus* B, enteritides, Flexner, Shiga and several other Gram-negative bacilli, was not affected by this concentration of the chemical. This inhibition may also occur *in vivo*, but in addition to this effect of the drug it is felt that the micro-organism must also be damaged to permit of a marked degree of phagocytosis by the leucocytes. On the other hand, the experiments of Mellon, Gross and Cooper showed no indication that phagocytosis is a factor in the mechanism of the therapeutic action of this drug, and this seems to be borne out by the fact that the pustular discharge in acute gonorrhœal urethritis begins to diminish about four hours after the ingestion of large doses of sulphanilamide. The question of the mode of action is therefore unsettled.

Toxicity.—All of our 134 adult patients tolerated 80 grains of sulphanilamide daily for four days without ill effect. It is known that some patients have tolerated $\frac{1}{2}$ of a grain per pound of body weight daily for a month without serious results. Six of our patients developed skin rashes during the period of maximum dosage. In all six the eruption occurred after exposure to sunlight and was confined to the hands and face, there being sharp lines of demarcation at the rim of the collar and the bottom of the sleeves. In four of the patients the eruption was urticarial, in one a mixture of urticaria and dermatitis, and in one dermatitis only. The urticaria cleared up within twenty-four hours after discontinuing the drug and did not recur when the medication was resumed with half the former dosage.

All of our patients were conscious of a drug effect, which varied from a slight feeling of dizziness or lassitude to a definite inability to do work which required mental concentration. Headache, when it occurred, was not severe. There were no cases of acidosis and only two of fever (routine temperatures were not taken). One patient developed a condition suggestive of methæmoglobinæmia, which disappeared in a few hours when the drug was stopped and did not recur when treatment was resumed with a smaller dosage. Complete blood counts have been done on more than one hundred of our patients and no changes attributable to the treatment have been noted. The gastric analysis in 8 of our failures showed normal acidity. No renal changes were noted. It should be borne in mind however that in case of renal impairment retention of the drug in the blood occurs. In short it would appear from the study of the literature and from personal observation that sulphanilamide is relatively non-toxic.

Absorption and excretion.—Marshall, Emerson and Cutting have shown that in the dog absorption from the gastro-intestinal tract is rapid, being usually complete or nearly complete in four hours. In patients when large amounts of sulphanilamide are administered daily in divided doses nearly 100 per cent may be recovered from the urine when equilibrium between intake and output is established. It takes from two to three days to establish this equilibrium and the same time to free the body of the drug after it is discontinued. Subcutaneous injection of the substance does not lead to higher blood concentration than when it is given by mouth. It passes readily into the tissues and is found in the cerebro-spinal fluid in only slightly less concentration than in the blood. The optimum concentration in the blood stream is 1:10,000 and this is easily obtained by rather large initial doses of the drug and is maintained by considerably smaller doses. A method for determining the blood level has been described by these authors and more recently a simpler and more sensitive modification has been described by Marshall. The human subject excretes the drug partly unchanged and partly conjugated in the form of an acetylated derivate.

CLINICAL OBSERVATIONS

Sulphanilamide treatment of 51 male patients was begun on 15th May, these being the ordinary clinic run

of patients attending on that day, and no selection of patients was made. Some had resisted the ordinary clinic treatment for months, and the common complications of the disease were represented in this preliminary group, including 1 of acute prostatitis, 5 of chronic prostatitis, and 1 of epididymitis. From day to day additional cases were started on sulphanilamide, to bring the total of this series to 30 females and 104 males. The diagnosis of gonorrhœa was confirmed routinely in each case by the demonstration in the laboratory of typical intracellular diplococci in the methylene blue stained smear of the urethral discharge. In the females smears were also made from the cervix. This was checked by the independent examination of duplicate smears stained by Gram's method in the Provincial Laboratory. Of the 30 female cases in this series all had positive smears within the five days preceding the institution of the sulphanilamide treatment. All the patients were ambulatory except one with acute prostatitis.

Of the males the first 51 of the series varied as to the duration of the disease from one day to several months; the succeeding 53 cases were all recently acquired infections of from one to five days' duration and coming under treatment for the first time. In the entire series of 134 adult cases the treatment consisted of: (1) 80 grains of sulphanilamide daily for the first four days; 40 grains daily for the second four days and 20 grains daily for the next seven days. The daily dose was divided into four equal portions and given every four hours from 8-00 a.m. to 8-00 p.m. (2) Each patient was instructed to drink large quantities of water and milk; all other fluids were prohibited. Other than this no instructions were given as to diet. (3) No local treatment of any kind was administered to any of these patients. Other patients treated in the clinic but who disappeared before completing the course, even though they appeared to be cured, have not been included in this series.

The cured patients have been followed for periods varying from one month to more than three months subsequent to the conclusion of the treatment. Relapses have occurred up to three weeks following an apparent cure, and although re-infection could not be ruled out these cases have been listed with our failures. Five of our uncured patients were placed in hospital, and for a period of five days were given prontosil subcutaneously in doses of 10 c.c. every four hours, or a total of 250 c.c. for each patient. In four of them the disease was not influenced by the treatment; the fifth case was very much improved but not cured. Our determination of a cure in the male was based on the absence of gross pus or shreds in the first and second glasses of urine and by the demonstration of not more than eight pus cells per oil-immersion field in the prostatic fluid; in the female by a series of not less than ten negative daily smears from the urethra and cervix.

Of our total of 134 cases 87.3 per cent were cured. Of the 104 males 91, or 87.5 per cent, were cured, 6 in one day, 13 in two days, 25 in three days, 14 in four days, 8 in five days and 25 in six to fifteen days; of the 30 females 26, or 86.6 per cent, were cured, but it is difficult in the females to decide just when the cure was effected. The females were seen and smears were made daily, some for as long as two months. In all cured cases the smears became negative within two weeks and symptoms of the disease disappeared. Of the 17 failures in this series not one seemed to be influenced by the drug. No complications whatever occurred in any of our patients during treatment.

One should approach the task of evaluating the curative effect of a new drug with an attitude of scepticism. Too often brilliant therapeutic successes have in the end proved to be due to optimism on the part of the observer. Many more cases will have to be observed over longer periods of time before a final decision can be reached, but the preliminary results would seem to indicate that sulphanilamide is of outstanding merit in the treatment of gonococcal infections.

SUMMARY

1. Twenty-six, or 86.6 per cent, of 30 females and 91, or 87.5 per cent, of 104 males affected with gonorrhoea were cured within fifteen days by a course of treatment consisting solely of the oral administration of sulphanilamide and large quantities of fluids.

2. No complications occurred in any of the patients in this series subsequent to the commencement of sulphanilamide therapy.

3. The total dosage of sulphanilamide given to each patient was 620 grains during a period of fifteen days.

4. The drug sensitizes some patients to sunlight which produces an acute urticarial eruption on the exposed skin.

Sulphanilamide in Gonorrhoea

(From the *British Medical Journal*, Vol. II, 6th November, 1937, p. 918)

THE treatment of bacterial infections with sulphanilamide and related substances was discussed last week at the Royal Society of Medicine, when Dr. Leonard Colebrook drew attention to some of the toxic effects that may arise. Dr. G. A. Buttle in an account of experimental work said that the gonococcus was as susceptible to sulphanilamide *in vitro* as the meningococcus, and for the moment interest is focused on the possibility of treating gonorrhoea with this drug. Since the demonstration by Proom that sulphanilamide is effective against experimental infection with the meningococcus, it has been assumed for the purpose of therapeutic trial that the gonococcus is also susceptible, and the truth of this assumption is now confirmed by Levaditi and Vaisman. These authors have succeeded in producing what appears to be true infection by the gonococcus in mice by the manoeuvre, suggested originally by Miller and Castles, and used by Proom in his work with meningococcus, of adding mucin to the inoculum. On the clinical side there are now several favourable reports. It appears from his study that most cases both of acute and of chronic gonorrhoea respond rapidly to the treatment, while a few seem entirely resistant to it. It is not clear that this resistance depends altogether on the anatomical location of the disease, and since the gonococcus is, serologically at least, a heterogeneous species, it may well be that resistance to sulphanilamide is a property of certain types of this organism. This is one of several matters which await investigation, not the least of which is the later results of the treatment. Dr. Cokkinis's report, like others which have already appeared, is of a preliminary nature. Meanwhile, there is news from Germany of further progress in this direction. Grutz, having experienced complete failure in the treatment of gonorrhoea with prontosil, and moderate success only with prontosil album (sulphanilamide), reports successful clinical trials of four new compounds which are said to be of similar nature; their actual composition is undisclosed and they are not yet available commercially. It cannot be emphasized too strongly that treatment with sulphanilamide requires close and expert supervision; success is evidently dependent on heavy dosage, which demands careful control if various toxic manifestations are to be avoided. These, according to numerous accounts, include, besides sulphæmoglobinæmia, which is now almost familiar, a skin rash and fever about the seventh day of administration, bone marrow changes leading to anæmia or even a fatal agranulocytosis, and optic neuritis. These more serious effects are fortunately rare, but it is nevertheless necessary when this drug is given that every facility should exist for their early recognition. The possibility of self-administration envisaged by Dr. Cokkinis when the public comes to recognize that gonorrhoea can be cured by swallowing tablets is alarming, and the sooner sulphanilamide and allied compounds are scheduled as dangerous drugs the better. Another warning appears necessary at this stage. The constantly expanding sphere of useful application of this drug may easily lead to its being looked upon as

a 'cure-all' for infections generally. Although, as Dr. Cokkinis points out, it may have a remarkable effect in a great variety of conditions, it must not be supposed that all cases of the diseases he mentions will respond to it. Susceptibility to this treatment is not a property of certain diseases in the anatomical sense, such as otitis, arthritis, and peritonitis; it is dependent on the identity of the micro-organism causing them, and an exact bacteriological diagnosis is necessary to intelligent therapy. The bacteria which have so far been shown to be susceptible to sulphanilamide are *Streptococcus pyogenes*, certain members of the coli-typhoid group, the meningococcus, and the gonococcus. The possibility of controlling pneumococcal and staphylococcal infections either with sulphanilamide or with other related compounds which are now being studied is still in doubt, and other bacteria, so far as is known, are insusceptible. The microbe rather than the regional diagnosis is thus the factor governing success or failure, and no observations which neglect this will add usefully to our knowledge of this remarkable remedy.

Prontosil and Similar Compounds in the Treatment of Puerperal Hæmolytic Streptococcus Infections

By G. F. GIBBERD, M.S., F.R.C.S., M.C.O.G.

(From the *British Medical Journal*, Vol. II, 1937, p. 695)

SINCE 1936 prontosil and similar compounds have been used extensively in the treatment of puerperal infections due to the hæmolytic streptococcus. Fuller has studied the chemical changes which prontosil undergoes in the body, and he has suggested that the active part of its molecule is sulphanilamide, so that the latter (simpler) compound probably acts in the same way as the more complex. At the isolation block of Queen Charlotte's Hospital prontosil was used in the first part of 1936, and streptocide (a preparation of sulphanilamide) has been employed since. As it is my purpose to study the clinical value of this group of drugs as a whole, I have drawn no distinction between the earlier cases treated with prontosil and the later cases treated with streptocide. I have referred to these drugs collectively as the 'new aniline derivatives' and to their use as the 'new chemotherapy'. Prontosil has been given by intramuscular injection and by mouth in daily doses of 20 to 60 c.cm. (0.5 to 1.5 grammes) intramuscularly, and 6 to 12 tablets (2 to 4 grammes) by mouth. Streptocide has been administered by mouth in daily doses of 8 to 20 tablets (2 to 5 grammes). The maximum doses have been given to patients who appeared to be severely ill, and these doses have been continued until clinical improvement has occurred. After this the dose has been decreased, but smaller amounts have usually been used for as long as a week after the temperature has fallen to normal.

THE NEW CHEMOTHERAPY

Some patients have developed marked cyanosis due to met- or sulph-hæmoglobinæmia, but in no case has this complication given rise to anxiety, and it has always disappeared on withdrawal of the drug. In a few cases of severe infection the use of the drug has been continued in spite of the cyanosis without any untoward effect. There does not seem to be any constant relation between the dose administered and the tendency to develop cyanosis. Apart from cyanosis no serious ill effects have followed the giving of these drugs.

These aniline derivatives have been used at the isolation block of Queen Charlotte's Hospital since January 1936, and I have to thank my colleagues on the clinical and laboratory staff for allowing me to report upon all the patients with hæmolytic streptococcal infections of the birth canal who were admitted from January 1936 until March 1937. It is now a routine practice to employ one or other of these drugs

in every case of hæmolytic streptococcal infection, but in the early part of 1936 there were some twenty patients to whom they were not given because of the mildness of the infection. These cases are included together with those treated by drugs during 1936-37 because I wish to show broadly what changes there have been in the results at Queen Charlotte's isolation block since the introduction of the new drugs rather than to give details of cases treated. As I have said it is not my intention to make any comparison between the earlier cases treated with prontosil and prontosil soluble and the later cases treated with sulphanilamide. The first group has already been reported upon by Colebrook, Kenny, and the staff of Queen Charlotte's Hospital. The second group will be the subject of a report to the Therapeutic Trials Committee of the Medical Research Council, and this report will subsequently be published. I have also given the results of cases of hæmolytic streptococcal infection admitted to the isolation block in the two years immediately preceding the introduction of the new drugs (1934-5).

There are thus two groups of patients to compare. The outstanding difference in the treatments in these two groups is that the new aniline derivatives were used almost as a routine in the one group and not at all in the other.

North-Western Fever Hospital, London, in spite of the fact that the new treatment was not used in that hospital, and they quoted Mr. James Wyatt's figures in this connexion. They pointed out, however, that the fall in mortality rate at the North-Western Fever Hospital had been progressive over a number of years, whereas there had been no such progressive fall at Queen Charlotte's. The fall from about 20 per cent to 4.7 per cent which they quoted from Queen Charlotte's was abrupt, and coincided with the introduction of prontosil into the scheme of treatment.

STREPTOCOCCAL INFECTION OF BIRTH CANAL AND ADJACENT TISSUES

Table I (b) shows that so long as the hæmolytic streptococcus is confined to the birth canal there is practically no mortality in either group; and table I (c) illustrates that even when the infection has spread to surrounding pelvic and lower abdominal tissues the patient almost invariably recovers, provided that widespread dissemination by the blood stream or by spread all over the peritoneal cavity does not occur. (The one death in the 1936-7 group which occurred in the absence of general peritonitis or septicæmia was due to a pulmonary embolus.) For proof that the infection has spread beyond the limits of the birth canal

TABLE I
Results of puerperal infections due to the hæmolytic streptococcus

	1934-5 GROUP			1936-7 GROUP		
	Number of cases	Deaths	Mortality, per cent	Number of cases	Deaths	Mortality, per cent
(a) Total number of puerperal infections due to the hæmolytic streptococcus	210	42	20	157	7	4.5
(b) Total number of infections clinically limited to the birth canal	98	0	Nil	104	0	Nil
(c) Total number of infections showing definite clinical evidence of localized spread beyond the limits of the birth canal (excluding septicæmia and generalized peritonitis)	50	0	Nil	30	1	3.3
(d) Total number of infections in which the hæmolytic streptococcus was demonstrated on blood culture (excluding cases in which generalized peritonitis was also proved)	28	11	40	21	5	20
(e) Total number of infections in which generalized peritonitis was proved to be present (excluding cases with septicæmia)	18	15	83	1	0	Nil
(f) Total number of infections in which both septicæmia and generalized peritonitis were proved to be present	16	16	100	1	1	100

Table I (a) shows that the gross mortality in the 1934-5 group was 20 per cent, compared with a mortality of 4.5 per cent in the 1936-7 group. The reduction in the mortality rate during the period when the new drugs were used is very striking. In their original reports Colebrook and Kenny considered the significance of these improved results, and were cautious in attributing them entirely to the treatment with the new drug. They drew attention to the fact that there had been a progressive fall in the mortality rate from hæmolytic streptococcal infections admitted to the

(apart from proved septicæmia or generalized peritonitis) reliance has been placed on the finding of a definite inflammatory mass in the pelvis or abdomen, and only cases in which such a mass has been demonstrated either clinically or at post-mortem examination have been classified under this heading.

These figures—table I (c)—show that the hæmolytic streptococcus is 'virulent' only in so far as it is invasive, and that a very large amount of tissue can be infected without causing death from absorption of toxins. In comparing the two groups of patients it will

be noted that in the 1934-5 group the infection was clinically limited to the birth canal in only 47 per cent of the cases. In the 1936-7 group the infection was clinically limited to the birth canal in 66 per cent. This may be interpreted in one of two ways. Either the prevalent hæmolytic streptococcus of 1936-7 was less invasive—that is, less 'virulent'—than that of 1934-5 or else the chemotherapy of 1936-7 helped to prevent the invasion of tissues around the birth canal.

In many cases of localized spread of infection beyond the limits of the birth canal it is difficult to say precisely when a definite inflammatory mass was demonstrated. Clinically a 'sense of resistance' may give place to a 'thickening', and it may not be until several days later that an obvious 'lump' is found. In spite of this difficulty an attempt has been made to give a figure indicating the proportion of cases in which an inflammatory mass developed after admission to hospital, that is, after the institution of treatment. In the 1934-5 series forty-one of the patients (20 per cent) had a demonstrable inflammatory mass on admission to hospital, and an additional twenty-nine patients (14 per cent) developed a mass some time after admission. In the 1936-7 series an inflammatory mass was found in twenty-seven patients (17 per cent) on admission to hospital, and in nine patients (6 per cent) a similar mass developed after admission. There was therefore a notable reduction in the proportion of cases in which an obvious spread of infection occurred after admission to hospital in the period when the new drugs were employed. This may be evidence of the efficacy of the new chemotherapy, or, alternatively, it may be explained on the grounds that the virulence of the hæmolytic streptococcus was diminished in the 1936-7 period.

MORTALITY RATES IN SEPTICÆMIA

Table I (d) shows the mortality rates in proven septicæmia (excluding cases in which general peritonitis was also proved). It was 40 per cent in the group of patients who did not receive the new drugs. Even 40 per cent may seem to be a surprisingly low mortality for blood-positive septicæmias due to the hæmolytic streptococcus, but in explanation of this I think that the care with which the bacteriological technique is carried out must be a factor in giving an (apparently) low mortality rate for cases in this class. If a less careful technique had been employed it is probable that some of the less severe septicæmias would not have been detected, so that although the total number would have been less the mortality rate would have been higher. This factor is of no importance in comparing the results in the two groups under review, because the technique of blood culture was identical in both. In the 1936-7 group the mortality for cases of proven septicæmia (excluding cases in which general peritonitis was also present) was 20 per cent; but before trying to assess the significance of this improvement it is useful to try to measure the severity of the cases in the two groups. Dr. Colebrook and his co-workers have, as a routine, estimated the number of organisms per cubic centimetre in the blood in cases of septicæmia, and as a general rule the clinically milder cases are associated with a lower count than the more severe. The records of these counts are not strictly comparable between various patients, because the number of organisms in the blood may vary greatly in different stages of the disease, and because blood cultures may be repeated more often in some patients than in others. Very roughly speaking, however, if the records show that a count of less than 10 organisms per c.cm. has not been exceeded at any time during the stage of pyrexia the septicæmia is probably 'mild'. The records of the cases at Queen Charlotte's Hospital show that the lower mortality from septicæmia in the 1936-7 period was associated with a relative increase in the proportion of 'mild' cases, in comparison with the 1934-5 period. This diminished invasion of the blood stream in the 1936-7 period is what we might expect to find if the new drugs were effective in checking the invasiveness of the hæmolytic streptococcus, but, alternatively, a falling off in the virulence of the prevalent hæmolytic

streptococcus of 1936-7 would also manifest itself in the same way.

In the 1934-5 group a positive blood culture was obtained within twenty-four hours of admission in thirty-one cases (15 per cent) of all cases infected with the hæmolytic streptococcus. In the 1936-7 group the corresponding figure was twenty-two (14 per cent). In the 1934-5 group ten cases (5 per cent) developed a septicæmia some time after admission. In the 1936-7 group only one patient developed a septicæmia (and in this case the first blood culture was not taken until several days after admission). The incidence of septicæmia before admission does not greatly differ in the two groups, and this is some evidence that there was not any considerable difference in the invasiveness (virulence) of the prevalent streptococcus in the two periods. If this is so the diminished incidence of septicæmia developing after treatment with the new drugs is some evidence that the good results are due to the drugs rather than to a hypothetical decrease in the virulence of the infecting organism.

GENERALIZED AND GENERALIZING PERITONITIS

Table I (e) and (f) gives the results when 'generalized' and 'generalizing' peritonitis occurred, but there are good reasons for exercising very great caution in interpreting these figures. The outcome of any peritoneal infection depends upon whether the tendency of the tissues to localize the infection overcomes the tendency of the organisms to generalize the infection, and the issue is often in the balance for some days. Unless laparotomy is performed, post-mortem examination is the only way in which a certain diagnosis of 'generalized' or 'generalizing' peritonitis can be made. The frequency at which laparotomy has been employed at Queen Charlotte's Hospital has varied from time to time, so that the opportunities for proving a diagnosis of 'generalizing' or 'generalized' peritonitis have also varied. It is not necessarily of significance, therefore, that there were thirty-four such cases in 1934-5, against two cases in 1936-7. Changes in proved post-mortem findings are, however, significant. In the 1934-5 group (210 patients) generalized peritonitis was found post-mortem in twenty-nine cases. In the 1936-7 group (157 patients) it was found post-mortem in only one case. The relative rarity of this proved necropsy finding in the latter group must mean either that the invasiveness (virulence) of the prevalent streptococcus was very much less in the 1936-7 group or else that the new chemotherapy was very effective in preventing the widespread dissemination of the infection.

RESULTS FROM THE NEW CHEMOTHERAPY

It is clear from the above analysis that since the introduction of the new chemotherapy there has been a very great improvement in the results obtained at the isolation block of Queen Charlotte's Hospital. The improved results are demonstrated: (1) by a considerable fall in the total mortality rate; (2) by a reduction in the proportion of cases in which the infection spread beyond the limits of the birth canal, and by the relative infrequency with which an inflammatory mass developed after treatment had been instituted; (3) by a significant fall in the mortality rate in cases of proved septicæmia associated with a relative decrease in the proportion of severe cases of septicæmia, and by a fall in the incidence of septicæmia developing after the treatment had been instituted; and (4) by the relative infrequency with which generalized peritonitis has been found post-mortem.

CONCLUSIONS

The new aniline derivatives have been employed at Queen Charlotte's Hospital since 1936; in the doses in which they have been given their use appears to be free from serious danger and has been followed by a very great reduction in the mortality rate for hæmolytic streptococcal infections. Analysis of the causes of this improvement in mortality rate shows that it is associated mainly with a decrease in the widespread

invasion of tissues by the hæmolytic streptococcus rather than with a greater tendency to resolution of the disease once widespread invasion of tissues has occurred. This feature makes it necessary to consider whether the improvement since January 1936 is due to the efficacy of the treatment or whether it is due to a change in the virulence of the prevalent organism. It is possible that both factors may be concerned. In non-fatal cases in which tissues beyond the limits of the birth canal have been invaded by the hæmolytic streptococcus there is some clinical evidence that the new drugs do actually hasten the resolution of the inflammatory process, and this is a good reason for believing that the treatment, rather than a change in the virulence of the organism, is responsible for the improvement in this direction.

While I am unwilling to guess how far the new drugs have been responsible for the undoubted improvement which has followed their clinical use, there is every reason to continue to employ them until their value or otherwise is firmly established.

The Use of Expectorants

By C. L. BROWN, M.D.

(From the *Journal of the American Medical Association*, Vol. CIX, 24th July, 1937, p. 268)

An expectorant may be defined as a medicine which aids in the removal of mucus or exudate from the lungs, bronchi and trachea. This action may be accomplished by causing a more active secretion, or by making the sputum more liquid or less tenacious. Another means of removal of sputum would be to stimulate the act of coughing, but this is seldom necessary or wise except in unusual states of debility in which large accumulations of sputum may actually imperil the patient. Often such a method would result in an expenditure of precious energy, and if possible aspiration should be employed instead. Coughing is nature's most efficient method of raising and ejecting sputum, and in some instances in which coughing is excessive, therapy must aim at controlling this act to allow the patient physical and mental rest and allow coughing at a time when it can be most efficacious.

To cough is to expel air, mucus or exudate from the lungs or air passages in a noisy, violent manner. When the respiratory mucosa is irritated by congestion, exudate or for some other reason, the nerve fibres transmit the impulse to the respiratory centre and the rather complex act of coughing is excited. Deep inspiration occurs, the glottis closes, and forced expiration is made. When the pressure becomes great enough to open the glottis, the sudden change in pressure is attended by the expulsion of a blast of air which characterizes the cough. If mucus or exudate is present in the lower respiratory tract it may be ejected with the air and the cough is 'productive'. If little or no exudate is present, or no sputum can be raised because of tenaciousness or for other reasons, the cough is said to be 'dry' or 'unproductive'.

In respiratory tract disease in which bronchial obstruction, diffuse or localized, is a part of the picture, there is a derangement of intrapulmonary and intrapleural pressures, the extreme of which is found in pulmonary emphysema. Mucus or exudate may cause partial bronchial obstruction to both inspiration and expiration. The forces of expiration are not as great as those of inspiration, and emphysema results from the accumulation of air in the alveoli and overdistention of their walls. Efforts to inspire air past the obstruction may be attended by increased negative intrapleural pressure, but if expiration is impeded greatly, as in obstructive emphysema, intrapleural pressure becomes elevated positively. In coughing, the forced expiration is accompanied by increased intrapulmonary pressure and elevated intrapleural pressure, simulating transiently the pressure changes found in emphysema, and, therefore, frequent prolonged unproductive coughing may be harmful. Since obstruction due to bronchial spasm or accumulation of sputum may respond to

medication, these factors should be carefully evaluated in the selection of expectorants.

Indications for expectorants most often arise in inflammatory conditions of the lungs and larger air passages, and since the same expectorant may not be efficient or advisable in the different stages of the disease, the proper selection depends on a thorough understanding of the underlying pathological condition. In allergic manifestations, such as bronchial asthma and asthmatic bronchitis, the degree of bronchial spasm and the character of the accumulated secretion serve as excellent guides in the choice of therapy. The clinical interpretation of the pathologic process is aided greatly by the close observation of the type of cough and expectoration. Furthermore, the art and science of the prescribing of expectorants is dependent on appraisal of the type of cough, the character of the sputum, and the correlation with the stages and clinical features of the causative disease. Four rather distinct types of cough may be recognized: the hacking, irritative unproductive cough, the 'tight' cough with scanty or tenacious sputum, the wheezy, squeaking cough, which may be either dry or productive, and the 'loose' cough with abundant sputum. In consideration of the subject under discussion, sputum has three main constituents, water, mucus and purulent exudate, and in the individual case it is necessary to evaluate the relative proportions of these components. In the early congestive stage of acute tracheitis, and bronchitis, the cough is of the hacking, irritative, unproductive type. After a few hours or even as much as from one to three days later it may become a 'tight' cough with scanty or tenacious mucoid sputum. In some cases of acute bronchitis, the squeaking, wheezing cough develops. Later in the disease the sputum becomes more abundant and mucopurulent and the cough loose. Bronchopneumonia may provide a similar change in the cough and sputum. Lobar pneumonia often has a type of cough and sputum characteristic of the disease, but generally the early stage has a tight grunting cough with scanty, more tenacious, mucopurulent and rusty sputum, while in the later stages the cough is loose and there is abundant, more purulent, sputum. Chronic bronchitis produces a thicker mucopurulent sputum, which at times is tight, at other times loose, depending on the abundance of the sputum, on the relative amounts of pus and mucus, and on associated bronchial spasm, and at times the cough may have a wheezy character. The cough of congestive heart failure is often rather unproductive until secondary infection in the bronchi or lungs appears; then it simulates that of chronic bronchitis. If pulmonary oedema occurs, the sputum is abundant, watery and frothy, and may be blood tinged. The wheezing, squeaking cough is characteristic of bronchial obstruction and is the type found in asthma and asthmatic bronchitis, and here the sputum is scant at first, later more abundant, and is tenacious and contains varying amounts of mucus and pus, depending on an associated bronchitis. In chronic pulmonary disease a loose cough with abundant purulent sputum usually means pulmonary suppuration with cavity, such as lung abscess, suppurative pneumonitis or bronchiectasis. In the latter conditions, coughing occurs when the exudate reaches the irritable level in the air passages, since the deeper portions of the lungs are rather insensitive to stimulation; thus the reason for postural drainage in such cases. The odour of the sputum may be a very good index as to the prolonged retention in the suppurating area. Although older writings have described a characteristic cough and sputum of tuberculosis, it is now recognized that almost any of the types mentioned may be found in pulmonary tuberculosis, depending on the type of pathological process present. As a general rule the appearance of gross blood in the sputum of chronic pulmonary disease calls for pulmonary rest.

Since the beginning of medicine the patient with a cough has expected and often demanded a 'cough medicine' as part of the treatment. A review of old authoritative works on therapeutics reveals numerous drugs of one kind and another used for this purpose,

a great many of them now obsolete, and provides an interesting historical background in therapy. Indeed, it would seem that the use of expectorants has been more of an art than a science.

Usually an expectorant is classified as 'stimulant' or 'sedative', and Sollmann has included a third group, the 'anodyne expectorants'. Perhaps such a classification serves some useful purpose, although it is difficult to list accurately the expectorant drugs under these three headings. There is some confusion in the definition of these terms; for example, one medical dictionary defines a stimulant expectorant as one 'used to expel secretions already formed'; one textbook on therapeutics refers to stimulant expectorants as those 'which are largely excreted in the bronchial mucus and which check the secretion or modify its character in some obscure way'; Fantus defines this class of expectorants as 'aromatic bodies that owe their virtue to elimination from the bronchial mucous membrane. Given in sufficient dosage, they possibly tend to favour healing by producing a curative hyperæmia'. Bethea, referring to Sollmann's classification, gives a practical correlation and clinical guidance as follows:

Sedative Expectorants: They are intended to soothe the acute inflammation mainly by stimulating the secretion of protective mucus. They may be nauseants, as ipecac; demulcents, as acacia or glycyrrhiza; salines, as ammonium chloride; alkalis, as ammonium carbonate. **Irritant (stimulant) Expectorants:** These are intended to irritate the mucous membranes in such way as to stimulate repair. They also tend to diminish excessive secretion. Some of these are also called aromatic expectorants. Typical of this group are terpin hydrate and creosote. **Anodyne Expectorants:** These are intended to depress the excessive cough reflex. These tend usually to diminish secretion. Codeine is typical.

Accordingly, the expectorant drugs official in the *U. S. Pharmacopæia XI* may be listed as in the accompanying table.

Expectorant drugs

SEDATIVE EXPECTORANTS—	Calcii creosotas
Ammonii chloridum	Guaiacol
Ammonii carbonas	Eucalyptol
Liquor ammonii acetatis	Oleum eucalypti
Potassii acetat	Oleum picis rectificatum (oil of tar)
Potassii citras	Syrupus picis pini
Sodii citras	Oleum terebinthinæ
Syrupus acidi hydriodici	Terebenum
Potassii iodidum	Terpini hydras
Calcii iodobehenas	Oleum pini punilionis
Antimonii et potassii tartras	Syrupus scillæ
Apomorphinæ hydrochloridum	
Syrupus ipecacuanhæ	
Mistura opii et glycyrrhizæ composita (Brown mixture).	ANODYNES—
	Morphinæ sulphas
STIMULANT EXPECTORANTS—	Codeinæ sulphas
Creosotum	Codeinæ phosphas
Creosoti carbonas	Aethylmorphinæ hydrochloridum

Ammonium chloride.—Ammonium chloride causes the sputum to be more fluid and less tenacious and may increase the quantity. Therefore, it is useful in the 'tight' cough accompanied by scanty or tenacious sputum, and this is most often seen in the acute and subacute inflammatory conditions (bronchitis and pneumonia) and asthma. Ammonium chloride is not indicated in the chronic stages when the sputum has become more abundant and easy to raise. Its effect does not last long and it should therefore be given at frequent intervals, perhaps as often as every two hours, and usually the dose of 5 grains (0.3 gm.) is satisfactory. It should not be prescribed with alkali hydroxides or carbonates. The following vehicles are especially suitable for ammonium chloride: syrup of citric acid, syrup of cherry, syrup of wild cherry, syrup of acacia, syrup of tolu balsam and elixir of glycyrrhiza.

Ammonium carbonate.—The drug has much the same indications as does ammonium chloride, although it is more irritating to the throat and stomach and in

large doses may act as a nauseant. With regard to dosage and frequency of administration, it should be used in much the same way as ammonium chloride. It is incompatible with acids and should not be prescribed with the syrups of acid reaction, such as those of citric acid, squill and ipecac. Although carbonates precipitate free alkaloids from aqueous solutions of most alkaloidal salts, codeine and atropine are not precipitated by ammonium carbonate.

Suitable vehicles for ammonium carbonate are syrup of acacia, elixir of glycyrrhiza and syrup of tolu balsam. Additional flavouring may be helpful in disguising the unpleasant taste, and for this purpose anise water, peppermint water and compound tincture of cardamom may be used.

Citrates and acetates.—Although some of the citrates and acetates have been used in the acute respiratory infections for their diuretic and indirect alkalinizing effect, they have been listed also among the expectorants, especially in larger doses, by many physicians. Representatives of this group of drugs are sodium and potassium citrates and solution of ammonium acetate and potassium acetate. When the citrates are to be used, the sodium citrate is commonly chosen and should be given in doses of 15 grains (1 gm.) every two hours, taken with at least 3 ounces (90 c.c.) of water. Either the sodium or the potassium citrate may be nicely prescribed in the syrup of citric acid or the syrup of orange. The acetates are somewhat less palatable and two common representatives of this group are solution of ammonium acetate and potassium acetate. The solution of ammonium acetate (liquor ammonii acetatis) is made from ammonium carbonate and acetic acid and should be used only when freshly prepared. The average dose is one-half ounce (15 c.c.) and is best given in one of the aromatic waters and flavoured syrups. Peppermint is especially recommended as a flavour. If acetates are to be prescribed, potassium acetate in 15 to 30 grains (1 to 2 gm.) doses in one of the aromatic waters and flavouring syrups is recommended.

Iodides.—Fantus states that 'iodide is the most powerful agent available for producing hyperæmia and exciting secretion of the respiratory mucous membrane', and 'therefore it is contra-indicated in acute bronchitis'. By the same reasoning it is contra-indicated in other acute forms of respiratory infection, such as the early stages of pneumonia. When the pathologic process is older and the sputum more tenacious, as in asthma or asthmatic bronchitis, the iodides may be very helpful. They are used against a thick sputum. Three official forms may be mentioned: potassium iodide, syrup of hydriodic acid, and calcium iodobehenate. The average doses given for these drugs are potassium iodide 5 grains (0.3 gm.), syrup of hydriodic acid 4 c.c., calcium iodobehenate 8 grains (0.5 gm.). If one considers only the iodine content in these drugs in the doses given, the amount of iodine is not comparable, the potassium iodide containing the most, the calcium iodobehenate being next, and the syrup of hydriodic acid containing the least. Potassium iodide is the simplest and most efficient form to prescribe if the iodide effect is desired. As saturated solution it may be given in five drop doses in milk after meals, or it may be prescribed in syrup of tolu balsam, syrup of orange, syrup of cherry or syrup of wild cherry, and syrup of pine tar. Syrup of hydriodic acid, in drachm (4 c.c.) doses every three or four hours, is prescribed ordinarily as such. The calcium iodobehenate is especially useful in cases in which potassium iodide causes gastric irritation and may be prescribed in its pure form without any vehicle.

Iodide should not be used in any case suspected of tuberculosis because of the danger of its increasing the activity of the disease.

Among the expectorants which are effective because of their nauseant action are ipecac, antimony and apomorphine. This group is indicated in acute respiratory infection in the early congestive stage when there is a 'dry' cough. The official preparations have been listed. Of these ipecac probably is the most used now

and is especially employed in the acute laryngeal, tracheal and bronchial inflammations in children. The syrup of ipecac may be prescribed as such, the dose being from 5 to 12 minims (0.3 to 0.7 c.c.), or it may be combined with some other expectorant indicated in the early inflammatory stage. Syrup of orange and syrup of tolu balsam are suitable vehicles for ipecac. Antimony in some form was formerly used widely as an expectorant but has become less popular. Antimony and potassium tartrate is commonly employed, the dose ranging from 1/60 to 1/20 grain (1 to 3 mg.), and syrup of glycyrrhiza, of orange or of tolu balsam makes a satisfactory vehicle. A large part of the expectorant action of the compound mixture of glycyrrhiza (brown mixture) may be attributed to its antimony content. Apomorphine hydrochloride is most often given subcutaneously, the average dose being 1/60 grain (1 mg.), although a satisfactory effect may be obtained by mouth.

The stimulant sedatives are most useful in the chronic inflammatory conditions. They tend to lessen the mucus and exudate and the hyperemia caused by them may aid the healing process. They should not be used in the acute stage because of the tendency to produce hyperemia. Creosote compounds and terpin hydrate, both aromatic, are the representatives of this group which will be discussed here. Both calcium creosote and creosote carbonate are satisfactory preparations and are used in much the same way. The average dose of calcium creosote is 8 grains (0.5 gm.) and of creosote carbonate 15 grains (1 gm.). Doses should be smaller at first. Usually an interval of four hours between doses is satisfactory. These drugs are especially useful when the sputum is abundant, as in lung abscess, bronchiectasis and suppurative pneumonitis. Many patients indicate that the sputum becomes less objectionable in taste and odour after taking these. Calcium creosote is best given in tablets. Creosote carbonate, in ascending (drop) doses, should be shaken up with milk.

Terpin hydrate is indicated in the chronic cough with abundant sputum and is said to be helpful especially against an excessive liquid sputum. It is commonly used in the form of elixir of terpin hydrate, which contains an insufficient quantity of terpin hydrate to give the best effect. For the full effect it is better to give terpin hydrate in capsules containing from 2 to 5 grains (0.13 to 0.3 gm.) three or four times a day. Elixir of terpin hydrate serves as a suitable vehicle for codeine.

Squill, not an aromatic but classified as a stimulant expectorant, has been used considerably in acute bronchial inflammation of children and in 'spasmodic croup', as the syrup of squill, usually in doses of from 15 to 30 minims (1 to 2 c.c.). At one time it was also said to be helpful in the 'winter bronchitis' of the aged. In the latter instance its good effect no doubt was related to the cardiac element in the so-called bronchitis. The syrup contains sufficient squill, if given in frequent doses, to produce some 'digitalis-like' effect and this should be kept in mind in its usage. The syrups mentioned are suitable vehicles, and other expectorants are sometimes added. Ammonium carbonate should not be put in syrup of squill.

The anodyne expectorants, so called, hardly need any comment, except to caution against their use in cases in which there is abundant purulent sputum. The purpose of the cough is to get rid of this exudate, and suppression of the cough reflex may be hazardous. Nevertheless, they are useful in giving the patient rest if coughing in such cases has tended to cause exhaustion. These drugs act by allaying the cough reflex, and the dose and frequency of administration are an individual problem. Codeine sulphate or phosphate are ones of choice; morphine should be avoided in treatment of the chronic cough because of the danger of addiction. However, there are occasions when good clinical judgment may dictate its use for temporary relief.

Diffuse partial bronchial obstruction as exemplified in bronchial asthma and asthmatic bronchitis presents a special problem in the use of expectorants. Both bronchial constriction and plugging by 'tenacious' mucus enter into this mechanism. Solution of epinephrine

1:1,000, in doses of from 3 to 12 minims (0.2 to 0.7 c.c.) given intramuscularly, is the most effective remedy for the bronchial spasm. Ephedrine hydrochloride and sulphate have a more prolonged effect and have the advantage of oral administration but are less certain to give relief. The ephedrine compounds in capsules are satisfactory, although they may be put in liquid preparations. Stramonium and belladonna, usually given as the tincture in a vehicle and often combined with some other expectorant, tend to diminish the quantity of the bronchial secretions. Potassium iodide is helpful in combating tenaciousness of sputum.

The availability of so many expectorants may cause difficulty in choice for a particular case. Most of the

PRESCRIPTION 1.—For acute bronchitis or pneumonia

R Ammonium chloride 10 gm.
Elixir of glycyrrhiza 60 c.c.
Syrup of acacia .. to make 120 c.c.
M. S.: One teaspoonful in half a glass
of water every two hours.

PRESCRIPTION 2.—For acute bronchitis or pneumonia

R Ammonium chloride 10 gm.
Syrup of citric acid .. to make 120 c.c.
M. S.: One teaspoonful in half a glass
of water every two hours.

PRESCRIPTION 3.—For acute bronchitis or pneumonia

R Ammonium carbonate 10 gm.
Compound tincture of cardamom .. 30 c.c.
Syrup of tolu balsam .. to make 120 c.c.
M. S.: One teaspoonful in half a glass
of water every two hours.

Prescription 4.—For subacute or chronic conditions

R Potassium iodide 10 gm.
Syrup of tolu balsam .. to make 120 c.c.
M. S.: One teaspoonful three times a
day, after meals.

PRESCRIPTION 5.—For asthma or asthmatic bronchitis

R Potassium iodide 15 gm.
Tincture of stramonium 20 c.c.
Syrup of tolu balsam .. to make 120 c.c.
M. S.: One teaspoonful three times a
day, after meals.

PRESCRIPTION 6.—For children

R Syrup of ipecac 5 c.c.
Syrup of orange .. to make 60 c.c.
M. S.: One teaspoonful every three
hours as necessary for cough.

PRESCRIPTION 7.—For acute conditions

R Compound mixture of opium and
glycyrrhiza 120 c.c.
S.: One teaspoonful every three
hours as necessary for cough.

therapeutic demands can be satisfied by skilful employment of a few representative drugs such as ammonium chloride, potassium iodide, syrup of ipecac, calcium creosote, terpin hydrate, codeine phosphate, epinephrine, ephedrine sulphate and tincture of belladonna. The selection of a suitable vehicle may be of no little importance in commanding the respect and co-operation of the patient. Syrups of acacia, tolu balsam, cherry, wild cherry and citric acid and elixir of glycyrrhiza furnish a fairly adequate choice.

Of the accompanying typical prescriptions, 1, 2 and 3 are to be used in acute or subacute inflammatory conditions (acute bronchitis, pneumonia) at a time when the cough is 'tight' and the sputum is scanty.

Prescriptions 4 and 5 are to be used in subacute or chronic inflammatory conditions when the sputum is thick, tenacious and more abundant. (Caution: Not to be used in tuberculosis.)

Prescriptions 6 and 7 are to be used in acute inflammatory conditions when the cough is dry or the sputum scanty.

Reviews

DISEASES OF THE BLOOD AND ATLAS OF HEMATOLOGY WITH CLINICAL AND HEMATOLOGIC DESCRIPTIONS OF THE BLOOD DISEASES INCLUDING A SECTION ON TECHNIC AND TERMINOLOGY.—By R. R. Kracke, M.D., and H. E. Garver, M.S. 1937. J. B. Lippincott Company, Philadelphia and London. Pp. xviii plus 532 including 44 coloured plates and 17 other illustrations. Price, 65s. Obtainable from Messrs. Butterworth and Company (India), Limited, Calcutta. Price, Rs. 48-12

The hæmatological renaissance, which dates from the important work of Minot, Castle and others on pernicious anemia and Witts, Mackay, and Vaughan on the iron-deficiency anemias of women and children, provides an interesting study for the medical historian. Some information might be obtained from a comparative study of the medical literature of ten years ago and of to-day. The successful book on hæmatology of the last generation was an atlas with a series of plates and short clinical descriptions, but with little attempt at classification or systematic arrangement of the material and no discussion on ætiology: in contrast to this, during the last few years, two, at least, of the best books on the subject have contained no plates, and the emphasis has been entirely on ætiology, on which the present-day classification is based.

From this point of view the publication of the present volume is a retrograde step, in that it is an hæmatological atlas: it is, however, a modernized hæmatological atlas and it will certainly fill a demand, even if this demand is not one that should be encouraged. The 44 full-page coloured plates are on the whole very satisfactory indeed. (The technical difficulties in the way of the production of perfect pictures of blood cells are at present insurmountable.) It would be easy to criticize individual plates or individual cells with such a vast choice, but if one picture does not satisfy one's idea of what the particular cell should look like, usually some other picture does. This was the reviewer's experience, with one exception; nowhere did he find a really satisfactory megaloblast.

The classifications given are in accordance with the modern tendency, but the arrangement of the material and the order in which the different disease syndromes are discussed seem to depend more on chance than on reason.

The chapter on technique is useful. With the wide scope for individual preferences criticism is again easy; however, we cannot see eye to eye with the writers on their method of sternum puncture, for example, they suggest the use of a mallet to pierce the anterior plate of the sternum (they are tough, mighty tough in the West!). They recommend the withdrawal of 10 c.cm. of fluid: there is no difficulty in obtaining this amount, but it will mean considerable dilution of the marrow blood from the circulation, and we can think of no examination that cannot be done with 2 c.cm.

In conclusion, we can say that the book is a useful addition to the literature as it contains an immense amount of valuable information and some good plates. We do not however recommend it to the young student of hæmatology lest it should lead him back into the old circular paths that lead through fields of morphological minutiae and cell genealogy back to the starting point, but we do believe that the trained worker will find it a very useful addition to his laboratory reference books.

L. E. N.

MINOR MALADIES AND THEIR TREATMENT.—By L. Williams, M.D. Seventh Edition. 1937. Baillière, Tindall and Cox, London. Pp. xiii plus 439. Price, 10s. 6d.

LEONARD WILLIAMS is an experienced and facile writer; he is always a pleasure to read; and he is as

near to being the ideal writer for the general practitioner as it is possible to be. As an editor and a writer in journals, he was always readable and amusing, though sometimes trivial, but in his *Minor Maladies*, a book which has now reached its seventh English edition, which long ago achieved classical rank, and which has been translated into both French and Spanish, he is at his very best.

A book of this kind is not quickly out-dated in the way that most textbooks are, so that much that appeared in the earlier editions still remains, but it has been polished and repolished so that it shines like pure gold in contrast to the dull base metals of the ordinary textbooks—and, we fear we must add, of some of the newer chapters of this volume.

He describes the *difficile* pre-tuberculous patient as 'not necessarily aggressive' but as showing a conspicuous absence of 'sweet reasonableness', as masterly a euphemism as the classical parliamentary 'terminological inexactitude'. Later, in the same chapter he reminds us that the sexual excesses of the reprobate youth who afterwards falls a victim to tuberculosis may have been caused by, rather than the cause of, early tuberculous infection. [It is difficult for us to shake off the shackles placed on our consciences by dishonest moral and religious teachers, who attempted to frighten us in our youth by emphasizing the avenging character of our god, or gods, and honestly to face the fact that the muscular excesses of a rowing 'blue' are likely to leave more scars on his physique than are the sexual excesses of the most unprincipled and most favoured youth.] The author considers that frequent colds do not predispose to tuberculosis but are rather an indication of the life these individuals lead—who, in short, live thoroughly unwholesome, coddling [Why not coddled?] lives, and thus cultivate within themselves an atmosphere, both physical and moral, in which the bacillus flourishes and multiplies exceedingly'. This is to a certain extent true, but it is not by any means only the coddled, or self-coddling, individual that is a 'martyr' to colds in the head or falls a victim to tuberculosis. On the other hand, we agree that 'the small ragged tonsils of an adult who no longer complains of sore throats are often more likely to require removal than the large succulent tonsils of a child'.

The chapter on minor dietetics is disappointing, though it contains many valuable truths. The author is inclined to rant against the 'modern dietitian', by which he really means the pseudo-dietitian. Modern dietetics has supplied a large number of incontrovertible facts based on accurate experiments, and if these facts are distorted by charlatan physicians or unprincipled commercial concerns it is scarcely the dietitians' fault. Further, we cannot agree with some of his rather dogmatic statements, e.g., on the relative value of food of animal and vegetable origin, and his advice to the physician to ignore calories.

Nevertheless, the book is still a classic and should be read by every doctor after he passes his final examination and before he sees his first private patient, and again and again unless he has an exceptionally retentive memory.

L. E. N.

A TEXTBOOK OF MEDICINE.—By American Authors. Edited by Russell L. Cecil, A.B., M.D., Sc.D. Fourth Edition. 1937. W. B. Saunders Company, Philadelphia and London. Pp. xx plus 1614. Illustrated. Price, 40s.

THIS textbook appears to have been one of the most successful of its kind in recent years and through its four editions has maintained its vital character. This can probably be accounted for by the multiplicity of the contributors, the frequent rewriting of sections, often by new contributors, and the addition of new sections on subjects that have recently assumed a greater importance. Though there are well over a hundred contributors, no lack of homogeneity is obvious.

The sections on tropical diseases are written in almost every instance by workers whose names are associated with these diseases through some original investigation that they have carried out, e.g., Bass on malaria, and Wolback and Pinkerton on the typhus group. Other sections are also written by well-known experts.

A surprising amount of well-arranged information has been crowded into the comparatively limited space allotted to each subject and the student or practitioner will find that he can acquire a very good outline of any medical subject from this volume.

Naturally, we have a few criticisms. The section on the treatment of malaria is very disappointing; it might have been written 30 or more years ago and touched up by the addition of the barest reference to the synthetic anti-malarials. The writer suggests the old 8-weeks' course of quinine and has not conveyed to the reader any idea of the unique properties of plasmochin.

In the typhus sections, classical typhus, Rocky Mountain spotted fever, trench fever, and tsutsugamushi disease are well described, but other typhus fevers are not taken into consideration at all. Nevertheless, tropical diseases as a whole get far better treatment than is usual in the one-volume textbook; for this and other reasons we consider it one of the best of the American textbooks on general medicine, both for the student and the practitioner.

L. E. N.

MALARIA AND ANKYLOSTOMIASIS IN THE PREGNANT WOMAN: THEIR MORE SERIOUS COMPLICATIONS AND SEQUELÆ.—By G. A. W. Wickramasuriya, F.R.C.P., F.R.C.S. (Edn.), M.C.O.G. 1937. Oxford University Press, London, Humphrey Milford. Pp. xii plus 179. Illustrated. Price, 10s. 6d. Obtainable from Oxford University Press, Bombay and Calcutta

THE author after years of practical experience in Ceylon is convinced that malaria and ankylostomiasis are very important factors in increasing the infantile and maternal mortality in that island. A reference to the textbooks and literature will show that most other workers in other tropical countries where these diseases are important are equally convinced of this same truth, most certainly as far as it applies to malaria.

It is of course very discouraging to set out to prove something that every one knows to be true if they only stop to think, it was therefore probably wise of the author to adopt the methods of the evangelist rather than those of the scientist in trying to drive home the truth to the unbeliever who will not pause and think. One of his favourite expressions is 'I am convinced beyond doubt that . . .', and whilst in most cases one feels that he is almost certainly right one cannot help regretting that he has not produced any scientific data, but has been content to report one or two cases in rather tedious detail, which is not always convincing, before writing his conclusions, which conclusions often bear little relationship to the previous matter in the chapter, are rather in the nature of the author's creed, and should, one feels, begin with the words, 'I believe'. For example, a patient with long-standing nephritis, pregnancy toxæmia, a heavy hookworm infection, severe anæmia ('30 per cent' hæmoglobin) and malignant tertian malaria was, amongst other things, given atebirin and died during labour: this incident appears to have shaken the author's faith in atebirin and led him to the sweeping conclusion that 'atebirin would appear to be contra-indicated in subjects of toxæmic pregnancy, pre-existing nephritis, and advanced hookworm disease'.

Whilst one is usually in sympathy with the author's beliefs there are occasions when the rationale of his treatment is a little difficult to follow. Why, for example, did he think it necessary to give two intramuscular injections of 0.032 grammes of plasmochin in a case of severe malignant tertian malaria at a time when the patient was 'very ill'?

The author is on a little less certain ground when he deals with hookworm infection, but here he gives

a comparative table which does suggest that hookworm infection complicates pregnancy. There are however a few points in this table about which one would like information. In his preface he says that 80 to 90 per cent of the inhabitants of Ceylon have a hookworm infection, yet only 30 per cent of his hospital cases were 'hookworm positive'. Does this mean that the latter were a selected population, or that he has excluded lower degrees of hookworm infection in preparing his table? There is no indication whether the author takes the view that, from a morbidity standpoint, only heavy hookworm infections are important or whether he adopts the argument of a certain fanatical helminthologist that as one egg in the stool spells hookworm-disease one need not worry unduly about the actual numbers; although he does give egg counts in his case notes he gives one no idea of what hookworm load he considers pathogenic.

The anæmia caused by hookworm infection is a very characteristic one and, even if complicated by pregnancy, maintains much of its original character, so that useful indications might have been obtained from the blood picture, but in no case is any detailed picture given, seldom more than the hæmoglobin percentage.

The book may be of value to obstetricians, and the author will certainly be able to say 'You have been warned' to his fellow practitioners in Ceylon and to obstetricians in other countries where malaria and hookworm occur, but one reader, at least, who is interested in the hæmatological aspects of anæmia in pregnancy and in the predisposing or causative rôles of these two infections in particular, found singularly little information of any value to him in this volume.

L. E. N.

THE MANAGEMENT OF THE PNEUMONIAS—FOR PHYSICIANS AND MEDICAL STUDENTS.—By J. G. M. Bullowa, B.A., M.D. 1937. Oxford University Press, London and New York. Pp. xvii plus 508. Illustrated. Price, 27s. 6d. Obtainable from Oxford University Press, Bombay and Calcutta

PNEUMONIA is a dangerous disease in any country; but its seriousness varies considerably from country to country, and it is in the United States of America that it is encountered in its most virulent form. In England—and probably elsewhere—pneumonia is known as 'the old man's friend', but in America old men apparently resent pneumonia's kindly services and prefer not to die. For these two reasons, in particular, an enormous amount of American money and the time of many of America's best scientists have been directed towards the reduction of the mortality from pneumonia. The results have been not a dramatic, but a very distinct, reduction in the mortality from this disease during the last decade or so.

In the book under review, after a preliminary chapter on classification and ætiology, the author goes straight to the bedside and discusses the problem of diagnosis, treatment, prognosis, etc., from data collected in his own experience and that at the Harlem hospital, and, though he lays particular stress on the fact that he has quoted only his own experience, his teaching is very much in line with the best American practice.

In treatment, emphasis is laid on the use of serum, particularly in type I pneumonia, in which in a large series, of nearly a thousand adults, the mortality has been reduced from 30 to 13 per cent. The importance of oxygen, given early and efficiently, is also stressed. As is usual in America, both alcohol and digitalis are condemned; alcohol is not recommended even in the case of the heavy drinker who has been used to a big daily dose.

The book is written for the student and the practitioner and will, we feel confident, be appreciated by both. Both will however find some of the tabulated data a little tedious, but they can easily skip this when reading the book. Also they may consider that some of the diagrams are slightly insulting to their intelligences; e.g., figure 26 on p. 78 is distinctly more

suited to a popular lecture than to a monograph written for physicians. On the whole, however, the book is an important contribution and contains much invaluable information: it is also very readable and is a book we can recommend to the practitioner for his personal library.

L. E. N.

THE CEREBRO-SPINAL FLUID.—By H. Houston Merritt, M.D., and Frank Fremont-Smith, M.D. 1937. W. B. Saunders Company, Philadelphia and London. Pp. x plus 333. Illustrated. Price, 22s. 6d.

IN the last years of the nineteenth century, Quincke introduced the examination of the cerebro-spinal fluid withdrawn by lumbar puncture, and since then it has become an invaluable aid in clinical diagnosis. It is now a routine method of investigation almost in every variety of nervous disease.

This book has been written from an analytical study of over 2,000 cerebro-spinal fluids and the clinical record of the patients. It shows the range of normal values and the various changes that have been observed in different pathological conditions. Techniques such as lumbar and cisternal puncture have been well described in a practical manner. A long chapter deals with the cerebro-spinal syndrome, the most heterogeneous group, such as, and trichinosis. The report of the fluids from 47 cases of spontaneous subarachnoid hæmorrhage with the tabulated results of four typical cases and similar data in various other conditions will prove very useful for reference. Therapeutic uses of lumbar puncture, roentgenography of the ventriculo-subarachnoid space and the biochemical methods have also been dealt with, thereby increasing the practical utility of the volume. Definite facts have been presented in such a way that one can match with considerable accuracy the findings of practically any case. There is an excellent bibliography and a differential diagnosis of the cerebro-spinal fluid in a tabulated form at the end of the volume. The book will undoubtedly prove very useful to those interested in nervous disorders.

R. C.

MEDICAL EMERGENCIES.—By C. Newman, M.D. (Cantab.), F.R.C.P. (Lond.). Second Edition. 1937. J. and A. Churchill Limited, London. Pp. x plus 150. Price, 8s. 6d.

THE distinction between a case which constitutes an emergency and one which does not is a little arbitrary. There are, of course, more surgical than medical emergencies, but, whereas in many surgical cases there are usually at any rate a few hours' grace, in medical ones treatment must frequently be instituted within minutes or seconds. For this reason, there seems to be scope for a purely medical volume. The publication of the second edition of this book further testifies to this fact.

The book begins with a chapter on poisoning, in which the symptoms and treatment of over sixty poisons have been described in about thirty-five pages. Such brevity, though desirable in a book of this type, is liable to misguide one to a wrong diagnosis. Next, the author deals with various emergent conditions such as Stokes-Adams' attacks, colics, pulmonary oedema, etc., with brief but useful and practical points in each. A few conditions, such as quinsy, eclampsia, threatened abortion, etc., which strictly speaking are not medical, have also been included; these will perhaps be appreciated by the general practitioner. But one is surprised to read in this book that it is the pneumonias and not blackwater fever which need quicker diagnosis and attention. In connection with the treatment of malarial coma it has been mentioned that one intravenous injection of quinine hydrochloride is sufficient to cure it; one would hesitate to make such a bold statement. The author recommends this book to be used as a companion to his surgical volume.

R. C.

PRACTICAL PROCTOLOGY.—By L. A. Bule, A.B., M.D., F.A.C.S. 1937. W. B. Saunders Company, Philadelphia and London. Pp. 512 with 152 illustrations, some in colour. Price, 30s.

ANY notable publication by a senior member of the surgical staff of the Mayo clinic may be rightly expected to receive a cordial welcome. In a brief foreword, Dr. Charles Mayo records his appreciation of the author's work. This handy volume, consisting of 512 pages and 19 chapters, is based on the personal experiences of the author as the head of the department of proctology for a period of ten years. Although the presentation, in this book, of the newer methods and recent advances is commendable, yet a certain lack of fine adjustment and correct appraisal of importance in the treatment of the subject-matter would seem to detract from a deserving success. For instance, we are told that one out of every seventeen patients in the department of proctology had cancer of the terminal colon and anus, and one out of every four had received treatment for some other supposed ailment. Yet there are only two short paragraphs on operative treatment!

The first chapter deals with the indications for investigation and the technique of examination. The position that is recommended for the patient is the 'inverted position', which is not in general use in this country. The improved pattern of proctoscope has obvious advantages in having the circumference of the barrel made to correspond with that of the index finger. The next two chapters deal with surgical anatomy, pre-operative and post-operative treatment. It is of interest to note that, in the hands of the author, sacral block anaesthesia has been successfully used in more than 15,000 cases. The two succeeding chapters are devoted to the consideration of cryptitis, papillitis, anal fissure and fistula. Hæmorrhoids, rectal prolapse and anal pruritus are then discussed in some detail. To the difficult subject of ulcerative colitis a whole chapter has been devoted, and amœbic and bacillary dysentery have each been accorded a separate part. Other chapters deal with colonic diverticula and polypoid disease. The section on malignant disease of the rectum, taken as a whole, is inadequate and therefore disappointing. Although it is loaded with a mass of statistical figures, the vital subject of treatment is dismissed with scant attention, as, in the opinion of the author, any discussion of the merits of different types of radical operation would be outside the province of this volume. Yet there are several pages on radium treatment and fulguration! A brief account of the author's own surgical practice would have enhanced the value of this section. The chapters which follow deal with melanosis coli, rectal stricture, venereal diseases and rectal granuloma and pilodanal disease. The final chapter, which will be much appreciated, is devoted to dietary formulæ and prescriptions.

There will be general agreement that this is a book of considerable merit. It would be of value to the general practitioner, but to be of greatest utility to the practising surgeon it would require amendments to which reference has already been made. The printing, get-up, and illustrations are all excellent. There is also a useful index.

P. N. R.

A PRACTICE OF ORTHOPÆDIC SURGERY.—By T. P. McMurray, M.B., M.Ch., F.R.C.S. (Edin.). 1937. Edward Arnold and Company, London. Pp. viii plus 471. Illustrated. Price, 21s.

A PRACTICE of orthopædic surgery in 458 quarto pages of small pica with one hundred and seventy-eight illustrations is something of a feat, even if the extensive subject of fractures, as in this case, is omitted. The reviewer perhaps expects the word 'practice' to include more than it should. It is not clear for what class of reader the book is intended. The absence of discussion on operative treatment reduces its appeal to the specialist and while the subject is handled dogmatically the student will hardly find time to digest the contents in an already overcrowded curriculum.

The book should find its best supporters among junior house surgeons beginning a specialist career. The practical side is stressed and while selected lines of treatment only are described these are given with clarity and precision. General practitioners requiring a succinct guide to the possibilities of modern orthopaedic surgery will find this book a readable and reliable guide. The x-ray reproductions are good and well chosen and none are indistinct. The author has avoided a redundancy of rare and peculiar specimens more suited to a monograph than a general handbook. Some of the outline drawings are crude and at least one in the peripheral nerve section is inaccurate. The price, 21s., is somewhat high.

H. R. H.

BODY MECHANICS: IN THE STUDY AND TREATMENT OF DISEASE.—By J. E. Goldthwait, M.D., LL.D., L. T. Brown, M.D., L. T. Swalm, M.D., and J. G. Kuhns, M.D. Second Edition. 1937. J. B. Lippincott Company, Philadelphia and London. Pp. xiv plus 293, with 100 illustrations. Price, 18s. Obtainable from Messrs. Butterworth and Company (India), Limited, Calcutta. Price, Rs. 13-8

MUCH attention has been paid in recent years to 'body mechanics' in the study and treatment of disease. Body mechanics has been defined by the White House Conference on Child Health and Protection, 'as the mechanical correlation of the various systems of the body with special reference to the skeletal, muscular and visceral systems and their neurological association'. In the present volume, this important subject has been carefully discussed with the hope that in the better understanding of the special structure and physiology of the individual, the solution of the problem of chronic disease will be largely found. The condition of poor muscular tone and faulty carriage is seen not only in childhood but in all periods of life. During the world war, we are told, no less than 46 per cent of the young men of Massachusetts were considered unfit for active service.

The book under review consists of fourteen chapters of which the first three deal with general considerations of 'body mechanics'. In the next chapter the three familiar body types are discussed, due regard being paid to the differences of susceptibility to disease. In the four succeeding chapters, important subjects, such as backache, arthritis, diseases of the abdominal viscera, and of the circulatory and nervous systems, are considered from the aspect of 'body mechanics'. Two chapters are devoted to treatment which include planned exercises, retentive apparatus and muscle re-education. Some illustrative cases are briefly recorded and these will be found of interest. The two concluding chapters deal with visceral disturbances and also public health aspects of body mechanics.

It is, in fact, a book to read and ponder over. But it suffers from one great defect of having been written with such manifest enthusiasm as is likely to be mistaken for rank partisanship, akin to fanaticism. The authors have been led to ascribe to faulty body mechanics, the origin, in part at least, of malignant disease of the genital organs in the female (p. 47) and prostatic enlargement in the male (p. 115). They believe 'that faulty body mechanics with its increased demands upon the energy of the motor tracts, and with accompanying congestion of the cord, may play a part in the onset and development of the muscular atrophies' (p. 153). There is one inexplicable omission in that there is no reference to the baneful effects of modern footwear, particularly in the case of the female. The book has been written in clear and simple language, but there are some rather unfamiliar terms, such as 'mechanistic features', 'acute medicine', 'visceroptotic existence', etc. The printing, get-up and illustrations are excellent and the bibliography is exhaustive. The book is dedicated to the chronic patient.

P. N. R.

A MANUAL OF OBSTETRICS.—By T. W. Eden, M.D., C.M. (Edin.), F.R.C.P. (Lond.), F.R.C.S. (Edin.), F.C.O.G., and E. Holland, M.D., B.S. (Lond.), F.R.C.P. (Lond.), F.R.C.S. (Eng.), F.C.O.G. Eighth Edition. 1937. J. and A. Churchill, Limited, London. Pp. xii plus 765, with 12 plates and 398 illustrations in the text. Price, 24s.

EDEN'S *A Manual of Obstetrics* has been a 'classic' for over 30 years. As one cannot criticize it and yet hesitates to praise it, beyond saying that it maintains its own high standard in its eighth edition, for fear of appearing to patronize two of London's leading obstetricians, one is compelled to record additions and changes and in doing this one cannot do better than quote from the preface.

In part I simplification of the sections on sex-physiology has been made possible by the work of the past five years on the chemical purification of the ovarian hormones and, in general, on the endocrine control of reproduction. The section on antenatal care has been amplified and made more practical, and modern views on diet during pregnancy are discussed.

In part II the section on the anæmias of pregnancy has been rewritten; so also has the section on pyelitis of pregnancy, in the light of radiological and therapeutic discoveries. The section on abortion contains the new work on endocrine and dietetic factors.

The sections on the aseptic conduct of labour and on obstetrical anaesthesia have both been expanded. Ergometrine comes in here—a drug of fundamental importance, which should replace the less safe posterior pituitary extract for routine post-partum use.

In part V (the puerperium) the new work on the sources and treatment of puerperal infections is probably of more fundamental importance than anything else in obstetrics during the last few years. This section has been almost entirely rewritten, and I believe everything of merit, including the grouping of the hæmolytic streptococci and chemotherapy by the prontosil group of drugs, will be found incorporated. Obstetric shock receives the attention it deserves.

In the treatment of asphyxia neonatorum the methods of artificial respiration have rightly fallen more and more into the background, whereas treatment by intratracheal insufflation has become more and more prominent.

Cæsarean section has been almost entirely rewritten and re-illustrated. The classical operation has been treated with the respect it merits; but the lower segment operation, which is slowly but surely rising into first place, has been given more space and a new set of illustrations.

We will conclude by saying that we hope that his 'Eden' will still remain the bible of the present-day medical student: practitioners will find sufficient important changes in this book to justify the investment in a new edition.

TEXTBOOK OF GYNÆCOLOGY.—By W. Shaw, M.A., M.D. (Cantab.), F.R.C.S. (Eng.), F.C.O.G. Second Edition. 1938. J. and A. Churchill, Limited, London. Pp. viii plus 616, with 4 plates in colour and 253 text-figures. Price, 18s.

THE first edition of this book was published only two years ago and met with the immediate success that it deserved. The author is a teacher at one of London's leading hospitals and knows what the student needs. In his treatment of the subject he is both precise and concise without necessarily being dogmatic, and though the book is not an exhaustive treatise, the subject is covered quite sufficiently for the M.B. student and for the general practitioner.

A new chapter in this edition is the one on hormonal therapy. Ten years hence it may be easy to write such a chapter; at present it is difficult on account of the many gaps and uncertainties in our knowledge of the action of most hormones. They have a habit of 'doing those things they ought not to do and leaving undone those things they ought to do'; as for example, though progesterin is indicated theoretically in dysmenorrhœa, in practice it is of little use, and, conversely, it is sometimes helpful in menorrhagia

where the rationale of its use is obscure. On the whole, this chapter is well balanced and will be a useful guide on the subject.

The book itself is attractive, the print is large and the illustrations numerous and very clear: there are also four excellent coloured plates. Altogether it is the ideal book for the student and practitioner, and makes a most suitable companion volume to Eden's *Manual of Obstetrics*.

TISSUE REACTIONS IN BONE AND DENTINE: A MORPHO-BIOLOGICAL STUDY OF THE FORMATION AND THE DISSOLVING OF BONE AND DENTINE.—By Ake Wilton, M.D. 1937. Henry Kimpton, London. Pp. 194, with 64 figures and 5 coloured plates. Price, 15s.

In this book the author has summarized his observations on the changes in the bones and dentine which take place both in the normal and abnormal conditions. He has tried to tackle this difficult problem more from the point of view of disturbances in the tissue biology rather than pathological alterations characteristic of the different diseases. The book is divided into two parts. In the first part the writer discusses the development of normal bone and dentine from the biological, morpho-biological and biochemical points of view and then tells us about the abnormal conditions which are brought about in rickets. He observes that the rachitic factor brings about a prolonged course of the differentiation of the bone and dentine cells and also an arrest of growth, these processes acting most strongly where the rate of growth is greatest. In the second part, the process of bone resorption is discussed both in health as well as in abnormal states, viz, in experimental hyper-parathyroidism, scurvy, Paget's disease, osteogenesis imperfecta, bone grafting and senile osteoporosis. Throughout the book, the author has tried to explain the real genesis of the normal development of bone and some of its diseases, by a cell mechanism which is influenced by a residual energy and the influence of the medium in which the cell has to act. This is undoubtedly a more rational way of approaching some of the skeletal diseases of doubtful aetiology than a mere study of their pathological picture and the author is to be warmly congratulated for this. We would confidently recommend it to everybody interested in the study of bone and its diseases.

M. N. D.

FOOD TABLES.—By V. H. Mottram, M.A., and E. M. Radloff, B.Sc., Ph.D. Edward Arnold and Company, London. 1937. Pp. 63. Price, 5s.

The last ten years has seen the addition to the practitioner's library of a very large number of books on dietary and food values, but it was still difficult to find a handy and cheap reference book in which one could look up quickly the 'food value' of any particular substance. The book under review supplies this need admirably.

Except for the preface the book consists of one large table. For each substance the values for four different weights are given, namely, 100 grammes, one ounce, four ounces and one pound; this facilitates calculation when one is working out the value of a diet. The values given are for protein, fat, carbohydrate, calcium, phosphorus, iron and calories: there is also a column of additional notes.

The table is a compilation and the sources from which the data are taken appear to be the most reliable.

The book will serve its purpose excellently. The Indian worker should use it in conjunction with *Health Bulletin* No. 23.

DIXON'S MANUAL OF HUMAN OSTEOLOGY.—Revised by E. B. Jamieson, M.D. Second Edition. 1937. Oxford University Press, London, Humphrey Milford. Pp. ix plus 465. Illustrated. Price, 21s. Obtainable from Oxford University Press, Bombay and Calcutta.

A SEPARATE textbook on osteology is somewhat of a luxury and not many have been published, but this

one will be a very welcome luxury to any medical student, and the teacher of anatomy might well look upon it as a necessity.

The information given is considerably more than a mere description of the bones and the attachments of the various soft structures and is by way of being an introduction to the study of anatomy. The figures throughout are excellent and there are some invaluable plates, mostly skiagrams of bones, which show their internal as well as external structure.

It is many years since this book was first published and in the first edition the B. N. A. nomenclature was used, but fortunately for the British student of to-day this nomenclature has been dropped in British schools and replaced by the much more pleasant Birmingham Revision (B. R.) of the B. N. A., and throughout this volume the B. R. nomenclature is used. It is a book we can recommend to both anatomical and surgical students and to their teachers.

BIOLOGICAL STANDARDIZATION OF THE VITAMINS.—By K. H. Coward, D.Sc. 1938. Baillière, Tindall and Cox, London. Pp. viii plus 227, with 44 figures in the text. Price, 12s. 6d.

RESEARCH work on human nutrition in India within the last few years has necessitated the acquisition of quantitative data on the composition of different food-stuffs, particularly as regards the vitamins. Recent diet surveys in this country have shown, for instance, that the appearance of signs of xerophthalmia is associated with a definite range of carotene intakes. Similar data for all the vitamins are clearly required for the prosecution of such investigations, and this volume supplies such a need. Apart from a discussion of the general technique of biological assay, complete details are given on what after all are essential points in this type of work, viz, type of animals, distribution of litters, effect of season of year on results, and methods for the mathematical treatment of data. The assays of vitamins A, B, C and D are treated with the international unit taken as the standard. The publication is essential for any laboratory concerned in the analysis of indigenous foods as a basis for diet and nutritional surveys.

H. E. C. W.

BIOLOGICAL AND CLINICAL CHEMISTRY.—By Mathew Steel, Ph.D. 1937. Henry Kimpton, London. Pp. 770. Illustrated. Price, 36s.

THE main object of this book is to promote the development of a more intimate relationship between chemistry, physiology and medicine, and the perusal of the book will convince the reader that the labours of the author have been well spent in that direction. The contributions of biochemistry to the progress of medicine, though recognized from very early times, have at no period in the history of medicine been of such paramount value as during the last few years. As a matter of fact it would be no exaggeration to say that applied biochemistry has played a most important part, not only in denuding it of empiricism but, what is more, in raising it to the present state of efficiency.

The present text differs from similar books on the subject in that the author has attempted to blend the theoretical and practical biochemistry with chemical pathology and clinico-chemical methods. The experiments described in the text are simple and the student is advised to do the test on himself so that he gets thoroughly acquainted, not only with the different techniques but incidentally begins to get an insight into the 'chemistry of diseases'. Thus, if he analyses his own stomach contents after a test meal, if he analyses his own blood and urine and performs clinico-chemical tests on himself, such as sugar tolerance, urea-clearance tests, etc., he gets a much better idea about such things as the influence of food and drugs on metabolism and is enabled to take a real interest in his experiments.

The idea of the author in making the student more chemistry-minded from the very outset is an excellent one and the perusal of the book in the light the author

would have it should be a great help to the student in getting a deep insight into the chemistry of diseases.

We gladly recommend the book to every student of medicine.

J. P. B.

PRACTICAL METHODS IN BIOCHEMISTRY.—By F. C. Koch. Second Edition. 1937. Baillière, Tindall and Cox, London. Pp. ix plus 302. Illustrated. Price, 10s.

THIS is an excellent handbook on practical physiological chemistry, intended for students going up for higher studies on the subject. The book has been written in an excellent style and the author has clearly and comprehensively dealt with the fundamental principles before describing the practical experiments.

The book has been divided into 3 parts, part I deals with the chemistry of cell constituents, such as carbohydrates, lipins, proteins, nucleo-proteins, nucleic acids, etc.; part II deals with the chemistry of the digestive tracts, such as salivary, gastric and intestinal digestion, and part III deals with quantitative analysis of blood and urine. In addition, there is a very useful appendix at the end of the book, dealing with such things as general laboratory instructions, special instructions for the use of instruments, such as colorimeters, etc., and detailed instructions for making standard solutions. In the strictly quantitative procedure of blood and urine analysis, only the more accurate of the rapid and practical methods have been given. This will be an advantage to the student who will not thus be confused with numerous other methods of doubtful value.

The revised method of doing the urea-clearance test by the direct Nesslerization method of van Slyke and modified by the author is a useful addition to the present edition.

We are of opinion that the book is a first class laboratory guide for students of biochemistry, and we have no hesitation in recommending it as such.

J. P. B.

MEDICAL BACTERIOLOGY—DESCRIPTIVE AND APPLIED INCLUDING ELEMENTARY HELMINTHOLOGY.—By L. E. H. Whitby, C.V.O., M.A., M.D. (Camb.), F.R.C.P. (Lond.), D.P.H. Third Edition. 1938. J. and A. Churchill Limited, London. Pp. ix plus 372, with 79 illustrations. Price, 11s. 6d.

THE medical curriculum becomes increasingly heavier year by year, but it is difficult to see how it can be pared down. An elementary knowledge of bacteriology is certainly essential to both the physician and the surgeon, but the textbooks on bacteriology on which students of the last generation were nourished have grown alarmingly and have now become handbooks, more suitable for those engaged in the practice of bacteriology or for students taking special courses. The book under review, which though in its third edition is new to the reviewer, would seem to supply the undergraduate student with all he need know about bacteriology and yet not more than he should be capable of assimilating in the hours that he can spare for this subject.

Our praise of the book must be general and our criticism specific: we should therefore like to print the former in bold-face and the latter in minute 4-point type, but the printer will not allow it. For the most part the compression has been done excellently and the really important point, the relationship of the micro-organism to the disease, is given due priority over detailed descriptions of the morphology and cultural properties of bacteria. The introductory chapters are concise, and just sufficient technical details are given to satisfy the needs of the student and the practitioner at the bedside.

On the other hand, the student and practitioner in the tropics have not been quite fairly treated. Rickettsia has been given only a page, and a quarter,

and this includes a table and a figure; not sufficient emphasis has been given to the proteus agglutinations, and only three types of typhus are given in the table; of these trench fever, which might well have been omitted, is one. Reference is made to a European form of rat-bite fever which is apparently neither transmitted by rats nor caused by *Spirillum minus*! Protozoa are of course included—though not mentioned in the title. Why is it that bacteriologists feel that they have the right to pilfer the protozoa without apology? Having done so they might at least treat them with more respect—‘three protozoal diseases, caused by organisms known as Leishmania’. We don’t say ‘written by a bacteriologist known as Dr. Whitby’, therefore why not ‘caused by Leishmania’ adding ‘a genus of protozoal parasites’, if thought necessary. And incidentally the disease caused by *Leishmania tropica* is not known as ‘tropical ulcer’, not in the best-informed circles, at any rate, as *ulcus tropicum* has quite a different aetiology.

Definite favouritism is shown to the helminths, who, despite the fact that they only needed 13 against the protozoans’ 14 pages, aspire to titular mention; ‘including elementary helminthology’ appears on the title page. It is certainly elementary, but still we think that some mention might have been made of how this ‘world producer of death, incapacity, and misery’ does his nefarious work, and how he obtains his own nourishment. The sentence ‘Severe microcytic hypochromic anemia is common’ concludes a paragraph on the anatomical description of the adult worm, and is followed immediately by a description of the ovum. The young student might be forgiven if he were a little confused.

Even the more advanced student might well be shaken by ‘nolenthan’ on p. 161, which at first we thought might be a patent American milk product but which we decided was merely an interesting misprint—interesting, because it must have come right through from the manuscript stage or from a later manuscript correction.

On the whole, however, the book is a valuable addition to the medical library and is very well suited to the needs of the M. B. student in this country; we strongly recommend it to him and to his teachers. The practitioner also will find it gives him as much of the subject as he will require in his everyday practice.

MEDICAL RESEARCH COUNCIL. SPECIAL REPORT SERIES, NO. 226. MEDICAL USES OF RADIUM: SUMMARY OF REPORTS FROM RESEARCH CENTRES FOR 1936. Published by His Majesty’s Stationery Office, London. 1937. Pp. 41. Illustrated. Price, 1s.

‘This report summarizes the work done with radium and radium emanation during 1936 at some twenty hospitals or other research centres, most of which hold radium on loan from the Medical Research Council; it thus continues the accounts given in the fourteen similar reports which have preceded it. It gives details of laboratory experiments on the fundamental aspects of irradiation and on the biological effects of radium upon cells and tissues, as well as of clinical methods used for the radium treatment of cancer. Statistical data relating to the after-histories of patients treated in earlier years have been included as before, and a new feature of this report is a section dealing with work at two centres on the use of massive radium units (telerradium therapy) for treating cancer’.

MEDICAL RESEARCH COUNCIL. SPECIAL REPORT SERIES, NO. 225. INVESTIGATIONS INTO THE NATURE AND CHARACTERISTIC FEATURES OF POST-NORMAL OCCLUSION.—By M. Young, E. Johnson, C. Smyth and M. Still. Published by His Majesty’s Stationery Office, London. 1937. Pp. 93. Illustrated. Price, 1s. 6d.

This report will be of considerable interest to dental surgeons and anatomists.

THE SCIENCE OF HYGIENE. SHWASTHYA BIGNAN. WRITTEN IN BENGALI.—By Radha Krishna Banerjee, M.B., D.T.M., D.P.H. 1937. Published by Kamala Book Depot Limited (15, College Square), Calcutta. Pp. 312. Illustrated. Price, Re. 1-8.

The author has very successfully undertaken the arduous task of getting up a standard textbook on elementary hygiene in Bengali for students preparing for the matriculation examination of the Calcutta University. In the attempt to use only vernacular terminology for anatomical parts, etc., the introduction of very uncommon synonyms has become inevitable and these 'unusual words' though scientifically accurate are rather difficult for elementary students: in fact, the exact meaning of many of the terms have to be referred to an Anglo-vernacular glossary furnished at the end of the book. The book consists

of eighteen chapters, namely, introduction, elementary anatomy and physiology, health, exercise and posture, environment, sunlight, air, earth, water, dwelling houses, food, origin and spread of diseases including bacteriology and control of spread of diseases, prevention of diseases, problems of social hygiene, smallpox and cholera, school hygiene, personal hygiene and mental hygiene—each chapter has been dealt with fairly elaborately—perhaps a little too elaborately for a matriculation student for whom hygiene is an optional subject: the information contained in these chapters is in a few instances almost up to the standard of the examination of the State Medical Faculty. A more critical reading and correction of the galley proofs would have obviated the rather confusing printer's mistakes, especially the one on the fourth page of the contents, which reads 'Benefits of narcotics' instead of 'The evil effects of narcotics'.

Abstracts from Reports

THE ROCKEFELLER FOUNDATION, NEW YORK: ANNUAL REPORT, 1936

In giving away 11,300,000 dollars during 1936 in connection with its world-wide programme, the Rockefeller Foundation co-operated financially with 130 agencies, in amounts varying from several thousand to several hundred thousand dollars; made available to scholars engaged in advanced scientific work 222 grants in aid, ranging in amount from a few hundred to a few thousand dollars; provided some 700 fellowships for post-graduate training of young men on whom will fall the burden of future leadership in fields of science, public health, and social welfare; made two large grants for endowment in connection with the closing up of a former programme; and conducted, by means of its own field staff of about seventy public health experts, researches on yellow fever, malaria, hookworm disease, tuberculosis, yaws, diphtheria, schistosomiasis, and influenza.

The agencies aided by the Rockefeller Foundation include 41 local and national governments, 44 educational institutions, such as schools, colleges, and universities, 20 research institutes, 2 libraries, and 23 councils, associations, societies, and commissions, most of them national or international in scope.

Work in 53 foreign countries was included in the foundation's programme of activities. The agencies with which it co-operated financially have a geographical range all the way from Scandinavia to Java. The funds appropriated for projects located in countries other than the United States amounted to 3,621,000 dollars, or about one-third of the total expenditures of the year. The balance was appropriated for projects conducted by organizations within the United States.

THE PURPOSE AND METHOD OF THE FOUNDATION

The purpose of the Rockefeller Foundation, written into its charter in 1913, is 'to promote the well-being of mankind throughout the world'. Changing conditions in scientific and social development must necessarily affect decisions as to how that purpose can best be realized. Nevertheless, for a decade or more, the advance of knowledge, with research as the chief tool, has been the definite objective and method of foundation action. The programme has extended into the fields of natural science, social science, medical science, the humanities, and public health. Except in public health, the foundation is not an operating organization. It conducts no researches of its own. Its efforts are limited to the support of other agencies—universities, laboratories, research institutes—where the promise of results seems particularly bright.

A programme concerned with the advance of knowledge runs the risk of scattering its resources over too wide a field unless a fairly definite policy of

concentration is adopted. Consequently, in natural science, the foundation has for several years placed its emphasis largely on experimental biology; in the social sciences, it has been particularly interested in problems relating to social security, international relations, and public administration; its work in the medical sciences has chiefly to do with psychiatry, broadly interpreted; in the humanities, it is working not so much on the content of humanistic studies as on the techniques by which cultural levels are affected, i.e., radio, non-professional drama, museums, libraries, and language problems.

These immediate interpretations of the ultimate objective of the foundation are, of course, subject to adjustment and alteration as conditions dictate. A programme that is too narrowly conceived and perhaps too long maintained can become ineffective and even sterile. There must always be the possibility and the inclination to change the strategy of attack in order to meet human problems that are new and challenging.

'THE PROPER STUDY OF MANKIND...'

A foundation that elects to follow a selective programme in enlarging the boundaries of knowledge is confronted with difficult questions. What special branches of knowledge should be enlarged? Is all knowledge equally important? Is anybody wise enough to determine the relative significance of different types of knowledge to a social order struggling for equilibrium?

The debate on these questions is, of course, worldwide. Uneasiness and even alarm are growing as the belief gains ground that the contributions of the physical sciences have outstripped man's capacity to absorb them. As General Smuts pointed out in his presidential address before the British Association for the Advancement of Science, there can be but little question that a serious lag has developed between our rapid scientific advance and our stationary ethical development, a lag which has already found expression in the greatest tragedy of history. A more recent president of the same Association, Sir Josiah Stamp, expressed the idea in these words: 'We are like a contractor who has too many men bringing materials on to the site, and not enough men to erect the buildings with them. . . . We are producing progressively more problems for society than we are solving. . . . Additional financial resources should be applied more to the biological and human sciences than to the applied physical sciences'.

It has been estimated that of all the money spent on research in Great Britain and the United States, one-half of the total goes for industrial research and for the underlying pure research in physics and chemistry. Of the remaining half, 50 per cent is spent on research in connection with military questions. Of the remaining quarter of the total sum, the larger part is devoted to

research in agriculture and the branches of biology which support it. Further down the list is research in medicine and public health. Finally come the social sciences with an infinitesimal fraction of the total devoted to their development. For research in the humanities the amount is relatively so small as to be scarcely discernible.

It is this consideration, among others, which has led the foundation to sharpen its programme.

Yellow fever.—Based on laboratory technique, a survey of the world by yellow fever immunity in man has been carried on during the past five years by the International Health Division, with the co-operation of the many governments concerned. The surveys of Africa and South America produced evidence of a much wider distribution of yellow fever than had been suspected. Details on the findings in Africa and preliminary data on immunity in South America have been published in previous annual reports of the Rockefeller Foundation. During 1936 there was published in the medical press information obtained in the yellow fever immunity survey of parts of the world other than Africa and South America. These investigations covered as many countries as seemed necessary, to determine the general boundaries between the recently infected and non-infected regions, and to show where intensive local surveys were required.

In addition to this method of obtaining information on the presence of yellow fever, now or in the past, another method has been developed which is based on the fact that yellow fever in man does much damage to the liver. In fatal cases a histopathological examination of the liver alone is frequently sufficient to establish positive or negative diagnosis of yellow fever. For the difficult conditions such as exist in rural areas in Brazil, where medical personnel is often not available to perform an autopsy when a fatal suspect case occurs and thus obtain a full set of tissues for examination, an instrument known as a viscerotome was developed by Yellow Fever Service. With this instrument a small portion of liver can be removed from a cadaver without an autopsy. The specimen thus removed is placed in a fixative and sent to the laboratory for examination. The viscerotome service is now so organized that in all cases in which death was preceded by acute fever a piece of liver tissue is removed by the local official who issues the burial permit. Up to present time over 60,000 liver specimens have been examined at the laboratories in Rio de Janeiro and Bahia.

When specimens showing pathological lesions suggestive of yellow fever are received at the laboratory from localities in rural areas, members of the field staff go into those localities and make a careful study of the conditions prevailing, and of any clinical cases that may occur there. If any of the persons examined show symptoms resembling those of yellow fever, blood is taken for intracerebral inoculation into mice for the purpose of isolating the virus. In addition, specimens of blood are taken from persons who have recently recovered from attacks of illness of a suspicious nature, and their sera are tested for yellow fever immunity.

It was by these procedures that frank cases of yellow fever were found and strains of virus isolated in rural areas where the inhabitants lived in widely scattered farm-houses with little communication among them, and where there were no *Stegomyia* mosquitoes, and even no mosquitoes of any kind. In other words, it was shown that yellow fever exists in the South American jungles, with an epidemiology that does not fit in with our past knowledge of the disease, which was based on information and data obtained in cities and densely populated areas. This has opened up a very broad and immensely difficult problem for study and it may be some time before there is full clarity in the picture of the so-called jungle yellow fever.

Yellow fever vaccination.—The vaccination of persons against yellow fever by the staff of the laboratories of the International Health Division began in 1931 and has progressed in three stages. The first, which lasted from May 1931 to January 1935, and employed the technique described above, accomplished its immediate

purpose of preventing further cases of yellow fever among investigators. It was not practicable for large-scale use in yellow fever control on account of the difficulty in obtaining and administering the necessary amount of immune serum. Research was therefore persistently directed toward the production of a strain of yellow fever virus that could be used safely without immune serum. As a result, the second or intermediate stage was reached in March 1935, when a beginning was made in vaccinating persons with a virus strain modified by prolonged propagation in tissue culture. This strain was still not sufficiently low in virulence to permit its use without immune serum. The threshold of the third stage has now been reached through further modification of virus strains by cultivation in tissues, an essentially time-consuming procedure. On 30th November, 1936, it became possible to use a modified virus strain of exceedingly low virulence, without previously injecting immune serum. It is hoped that this will make it feasible to apply active immunization to a much greater number of persons than was heretofore possible.

The nature of viruses.—The group of infectious agents known as the filtrable viruses has aroused much interest in recent years. A great deal is known regarding their harmful effect upon a susceptible host, whether plant, animal, or man. Nothing is known, however, of their exact nature. A fundamental study of the physical nature of viruses is exceedingly difficult. They do not exist in nature in a pure and concentrated form but are always associated with a large amount of protein matter originating from the host which they attack. They are strictly parasitic and propagate only upon living cells. Separation of viruses from the protein with which they are associated is very difficult, as most viruses are labile and easily inactivated by the chemical processes involved in such separation. No chemical or physical test is known by which the presence of a virus in a given material can be detected except by its specific action on a susceptible host.

During the past three years much time has been spent also in developing high speed centrifuges which could be used with advantage in the study of viruses.

The rotating part of the instrument is provided with a transparent quartz cell in which the sedimentation velocity of the material studied is recorded photographically while the centrifuge is running. The centrifuge has been run repeatedly at a speed of 60,000 revolutions a minute, and a centrifugal force of 260,000 times gravity has been obtained in the cell. It is hoped that this ultra-centrifuge will be an important tool for research, not only in the study of viruses but also in protein chemistry in general.

Some progress was made during the year in devising chemical procedures for the separation of the yellow fever virus from the associated protein without inactivating the virus itself. Virus-containing materials such as blood or tissues from infected animals were desiccated in the frozen state, fat was extracted by ether or petroleum ether, and separation of the various protein constituents from the virus was accomplished by fractional precipitation with saturated solutions of different salts. After most of the proteins were removed, the virus suspension was rendered salt-free by quick dialysis. The results indicate that yellow fever virus, although extremely labile under ordinary conditions, is relatively stable when kept in an anhydrous condition such as obtains in ether mixtures or saturated salt solutions. The final product, which shows only traces of protein by ordinary chemical tests, has lost a relatively small portion of active virus during the process. In its final stage it is highly diluted, but can be easily concentrated in the high speed vacuum centrifuge mentioned above.

Influenza.—Influenza studies which had been carried on during the two previous years by the Rockefeller Institute for Medical Research were taken over by the International Health Division of the Rockefeller Foundation at the beginning of 1936. Four members of the International Health Division staff devoted their entire time to these studies. A number of fundamental problems, chiefly relating to the characteristics of the

virus of epidemic influenza, were investigated during the year.

Scarlet fever.—A broad epidemiological study of scarlet fever was initiated during 1936 in Roumania, where conditions are favourable for the study of this disease. Interest centres upon factors producing epidemics, methods of spread, and development of control procedures.

Yaws.—Yaws might conceivably be controlled in one of three ways. Susceptible individuals might be immunized. At present there is no vaccine against yaws. Secondly, transmission might be interrupted. There has been some indication that a small fly called *Hippelates pallipes* might have something to do with yaws transmission. Such transmission in nature has not been proved. But even if these flies did mechanically transmit the disease, and if they could be controlled, the disease would still also be transmitted by contact. The third way in which yaws might be controlled is by treatment, and this is the method used in the yaws campaign in Jamaica with which the foundation has been associated. By a comparatively simple form of treatment the individual can be rendered non-infectious. Such treatment relieves suffering and cuts down the source of infection.

Syphilis.—The foundation has been co-operating with the Johns Hopkins University School of Hygiene and Public Health in the development of a health district in the city of Baltimore. The district serves as a practice field for students in public health. The school has undertaken epidemiological studies of syphilis in this area, and the foundation has assigned a staff member to assist in the investigations. Further aspects of the work include laboratory studies and the teaching of syphilis control to public health students.

Schistosomiasis.—For some years the foundation has co-operated with the Egyptian Government in studies aiming at the control of schistosomiasis, a disease caused by the liver fluke, and a serious public health problem in Egypt. This work was continued in 1936. The organism which caused the disease is carried by snails frequenting the numerous canals used in irrigation. Much research has been done on the life cycles of these snails for the purpose of arriving at a practical method of attacking the disease. To determine the effectiveness of canal clearance as a control measure alternate canals were cleared of weeds, plant refuse, snails, and ooze at two-month intervals, and others were left undisturbed for comparison. Surveys were made before clearance, during clearance, and after clearance, and snail reduction was found to be significant and gratifying. Clearance of canals is therefore proposed as a prime factor in any scheme for the control of human schistosomiasis in Egypt. It is efficient and inexpensive, and can be done satisfactorily by the ordinary workman.

Smallpox vaccine.—The foundation has co-operated with the Tennessee State Health Department, and with the Department of Pathology of Vanderbilt University, in research on the preparation of smallpox vaccine virus in embryo chicks within the egg. Attention is centered on the large-scale production of the new embryo chick smallpox vaccine.

Hookworm disease.—The only country in which the foundation is at present still co-operating directly in the control of hookworm disease is Egypt, where studies in the improvement of sanitation, especially by means of the bored-hole latrine, were continued during 1936.

Malaria.—By far the major part of the foundation's work in malaria concerns research and control efforts carried out in co-operation with communal and governmental authorities in many parts of the world.

In the work in Italy an attempt has been made to solve the engrossing problem encountered not only in that country, but in many parts of Europe, of anophelines without malaria. Studies indicated that the anopheline mosquitoes in non-malarious areas had little or no contact with man. This was determined by examining the blood taken from thousands of mosquito stomachs and identifying the species of animal from which the blood had been drawn. This led to the hypothesis that the anophelines in these places had a preference for animal blood, and that there were

probably two biological races of *Anopheles maculipennis*, one a man biter, and the other predominantly a cattle feeder. In the absence of any physical difference between these two types, the theory found little acceptance. A search was instituted for an identification mark between these different races of *Anopheles maculipennis*. Finally the solution appeared where it was least expected, namely, in the complicated and varied patterns of the mosquito eggs. Certain patterns of eggs were always missing in malaria-free areas. It turned out that these missing egg patterns belonged to the man biters, and the *Maculipennis* mosquito of Europe was not a homologous species, but divided into seven or more races of subspecies, all looking precisely alike, but laying different kinds of eggs. This clarified the whole malaria picture, both in Italy and in other European countries.

These diverse races of *Anopheles maculipennis* choose different types of surface water in which to lay their eggs. Some prefer marshes, some rivers, and some brackish water along the coast. It became possible to sharpen the attack on malaria by directing it against the dangerous forms of mosquitoes, ignoring the others entirely. The new light thrown on the subject of mosquito classification, therefore, led to important practical results. Recent investigations in many parts of the world show that the same condition holds for other widespread anopheline species that carry malaria; that is, certain species other than *Anopheles maculipennis* may also not be homologous, but may consist of different races with different life habits, all of which must be studied to make the attack on malaria more efficacious.

The Madras Presidency in India has been chosen as a suitable locality for malaria research in the East. Headquarters have been at the King Institute of Preventive Medicine in Guindy, which is seven miles south of Madras City. Laboratory investigations of simian malaria have been undertaken, and field work includes anopheline studies and a survey of the many wells in this area, which would come under consideration as mosquito breeding places in any campaign for malaria control.

[This abstract only briefly touches on some of the work of importance in the control of human disease, namely, that of the International Health Division of the Foundation. When it is stated that the report, excluding the financial statements, covers 332 pages our readers will understand that a full abstract is impossible so we are reluctantly compelled to ignore the other branches of its activities.]

ADMINISTRATION REPORT OF THE DIRECTOR OF MEDICAL AND SANITARY SERVICES, CEYLON, FOR 1936

Public health and general epidemiology

Western Province.—The recovery of the Western Province from the effects of the recent malaria epidemic has been, on the whole, very satisfactory. In Kukulura district the incidence of malaria has been normal since April. In Colombo district, during the latter half of the year, conditions closely approximated to normal. The improvement was least manifest in Negombo district where there was a moderate rise in the incidence in January and again in June and July.

Central Province.—In Kandy district, with the exception of Tumpane and Pata Dumbura, the incidence of malaria was practically normal. The almost complete disappearance of malaria from the hilly districts of Nawalapitiya and Watawala, which were more or less severely affected during the epidemic, is remarkable. In Nuwara Eliya district malaria was restricted to the lowlands of Walapane, where it has always been epidemic; the revenue divisions of Kotmale and Uda Hewaheta are now free save a few low-lying villages where a certain amount of malaria still persists. Except for a few localized outbreaks in North Matale and East Matale, where malaria is endemic, the malaria situation in this district showed steady improvement during the course of the year, and the recovery from

the effects of the epidemic was very marked especially in South Matala.

Southern Province.—In Galle district, the dispensary attendances, speaking generally, were rather higher than usual, but there were no outbreaks of disease. The incidence of malaria in the district was too low to seriously affect morbidity. During the second and third quarters of the year, the Wellaboda and Kanda-boda pattus of the Matara district were in the grip of a severe outbreak of malaria. The peak was reached during the week ending 11th July. Owing to the prompt action taken by the department and the provision of ample facilities for quinine distribution, the mortality rate was negligible. Normal conditions prevailed during October and November but in December a second wave occurred which synchronized with the north-east monsoon fever season. In Hambantota district, although no actual outbreaks of malaria occurred during the year, the general health of the population was much less satisfactory than usual. The greater part of this area is hyperendemic and malaria was directly responsible for 75 per cent of the total morbidity.

North-Western Province.—In Kuruegala and Chilaw districts the recovery from epidemic conditions had been tardy. At the beginning of the year malaria was responsible for nearly 70 per cent of the total morbidity but at the end of the year for only 50 per cent. In Puttalam district the conditions were practically normal until the end of October; but during the fever season (November and December) the incidence was high. The dispensary attendances rose to nearly twice and in some places as much as three times the 'expected' for this part of the year.

Northern Province.—Jaffna district experienced an unhealthy year. In January, February, and December, which are usually the most unhealthy months, the outdoor dispensary attendances were twice the normal, but malaria did not occur anywhere in epidemic form. During the fever season malaria constitutes about 60 per cent of the total morbidity, but during the rest of the year it is responsible for only about 20 per cent. In Mullaitivu district severe malaria prevailed till the end of May. Thereafter normal conditions prevailed until the onset of the fever season in November. Mannar district experienced, on the whole, a healthy year.

North-Central Province.—In this province malaria as usual was the predominant disease and was responsible for over 60 per cent of the total attendances. The year was throughout unhealthy but the worst months were January, February, March, and December.

Province of Sabaragamuwa.—In Kegalla district, the recovery from epidemic conditions was very satisfactory. Towards the end of the year the malaria situation closely approximated to normal. In Ratnapura district conditions were normal.

Province of Uva.—In this province malaria was responsible for about 20 per cent of the total morbidity. There were no outbreaks. The hilly districts that were moderately affected during the epidemic are now free from malaria. The increase in the number of cases treated in hospitals and dispensaries was due to causes other than malaria, mostly influenza.

Eastern Province.—In this province as usual malaria was the most prevalent disease. During the first six months malaria prevailed to a much greater extent than usual. The conditions closely approximated to normal in August, September, and October; but with the onset of north-east monsoon rains, there was a moderate rise in the incidence.

The most prevalent general diseases of hospital in-patients were rheumatism, intestinal disorders (diarrhoea and enteritis), bronchitis, and pneumonia. Year by year the number of patients who seek hospital treatment for cancer is increasing.

Plague.—The 57 cases of plague in 1936 show an increased incidence of the disease compared with the average for the previous five years (56). Of these, 45 cases were of the bubonic variety and 12 septicaemic.

Cholera.—There have been during 1936 49 cases with 44 deaths giving a fatality rate of 89.8 per cent. The

cases were all confined to the Eastern Province; 48 out of 49 cases occurred in Batticaloa district and one case occurred in Trincomalee district. There were two outbreaks—the first occurred in March-April and the second in October 1936. Forty-five cases with 40 deaths occurred in the first outbreak and 4 fatal cases occurred in the second.

The first outbreak occurred at Manmunai South in the vicinity of Kokkodicholai and Atuchenai. The disease first broke out among cultivators who went to the paddy fields in Manmunai South for reaping harvest. The first case occurred on 17th March, 1936, and proved fatal on the same day. The last case occurred on 17th April, 1936, and the last death on 18th April, 1936. The second outbreak occurred in Manmunai South and Porativu six months after the first outbreak. The disease broke out among cultivators of Natpathuwaddai near Atuchenai. The first case occurred on 6th October, 1936, and the last on 12th October, 1936.

The exact source of infection could not be definitely traced. In the first outbreak there is reason to believe that the infection had arrived from India from where labourers come periodically for work during harvesting seasons. The source of infection in the second outbreak which occurred almost exactly at the same spot as the first is probably a carrier in the locality. The mode of transmission in both outbreaks is considered to have been by contact. No common source of water supply could be incriminated.

Smallpox.—There were three cases of smallpox, all of which proved fatal. These cases occurred in Colombo in three Indian Tamils who arrived freshly from India. The first case was in a person who arrived in Colombo on 9th January, 1936, and fell ill on 11th January, 1936, and died on 22nd January, 1936. The second was in a person who arrived on 1st August, 1936, fell ill on the same day, and died on 13th August, 1936. The third was in a person who arrived on 30th September, 1936, fell ill on the same day, and died on 10th October, 1936.

Chickenpox.—Six thousand seven hundred and sixty cases as compared with 5,266 cases in 1935 were reported to the sanitary branch during the year with 12 deaths, giving a fatality rate of 0.18 per cent.

Diphtheria.—One hundred and three cases as compared with 116 cases in 1935 were reported to the sanitary branch during the year with 13 deaths, giving a fatality rate of 12.62 per cent. All the cases were of the faucial variety. On an average 9 cases were reported monthly, with the maximum 14 in May and the minimum 5 in March.

Measles.—Two thousand seven hundred and seventy-five cases as compared with 719 in 1935 were reported to the sanitary branch during the year with 2 deaths, giving a fatality rate of 0.07 per cent.

Mumps.—One thousand one hundred and thirty-five cases as compared with 485 in 1935 were reported with 5 deaths. On an average 94 cases were reported monthly, with the maximum 142 in November and the minimum 64 in December.

Whooping cough.—Two hundred and ninety-six cases as compared with 235 cases in 1935 were reported with 21 deaths, giving a fatality rate of 7.09 per cent. The incidence shows a rise in the months of November and December. On an average 25 cases were reported monthly, with the maximum 68 in December and minimum 7 in February.

Enteric.—The actual prevalence of the disease cannot be judged from hospital admissions since many cases resort to ayurvedic treatment and the majority probably are not notified. The number of registered deaths does not indicate the actual mortality from this disease, as some deaths from enteric are undoubtedly included amongst those reported as due to pyrexia. There were 14,520 deaths due to pyrexia in 1936, as against 22,507 in 1935.

Two thousand five hundred and three cases were notified in 1936 to the sanitary branch of this department as compared with 1,991 in 1935, with 449 deaths, giving a fatality rate of 17.8 per cent.

Dysentery.—Three thousand three hundred and thirty-three cases or 64.3 per cent of the total number of cases were stated to be amœbic and 1,067 cases or 20.6 per cent bacillary. These figures, however, are not of great value since the distinction was often made on clinical grounds. Only a small percentage of the cases were submitted to complete laboratory investigation and among them the bacillary type greatly preponderated. The mortality rates of amœbic dysentery were 11.7 per cent and of bacillary 10.7 per cent.

Tuberculosis of the lungs.—Four special institutions—the anti-tuberculosis institute, Colombo (out-door), Kandana Sanatorium, Western Province, and the Kankasanturai Sanatorium, Northern Province, for early cases, and the Ragama Tuberculosis Hospital, Western Province, for moderately advanced cases—are maintained to deal with this disease.

Leprosy.—During the year 1,253 cases with 74 deaths, as against 1,261 cases with 97 deaths in 1935, were treated at Government hospitals including the two asylums which are maintained in the island for the segregation of lepers.

Furs.—Owing to the decrease in the number of cases the itinerating medical officers who numbered 13 in 1930 were further reduced from 4 to 2 from 1933.

Hygiene and sanitation

Public health work made steady progress during the year, the latter part of which saw the launching of the malaria control and health scheme. This scheme has for its object the carrying out of health work on health unit lines, with special attention paid to malaria, which is made an integral part of general health work. The programme is to take up the whole of the island progressively, and when the work is fully organized and functioning it will no doubt have a marked effect on the improvement of the health of the people.

General sanitation continues to be satisfactory in urban and rural areas. The carrying out of work by co-operation through health leagues has become the policy of the department and good progress has been made.

The control of soil pollution through construction, maintenance, and the use of sanitary latrines is the chief work of sanitary assistants. The progress of this work is dependent on the provision of cement concrete squatting plates which are the only type of platform that is recognized. During the year 347 bucket latrines in urban areas, 13,639 deep pit latrines, 312 bored-hole latrines, and 263 mound latrines in rural areas were constructed, making a total of 17,901 latrines as compared with 9,562 latrines during 1935.

The provision of protected water supplies in urban and rural areas is a matter that needs most attention. Although the matter is before those concerned with their provision, still a large portion of the population lacks a wholesome supply of good drinking water. During the year 119 new public wells were constructed, as compared with 155 in 1935; and 1,667 wells were improved as compared with 1,569 in 1935.

The control of communicable diseases continues to receive close attention. With plague endemic in Colombo, infection from there is carried from time to time to towns in the interior of the island. During the year there were outbreaks of the disease at Anuradhapura and Hattton due to infection conveyed there in bags of rice. Anuradhapura, although a town in the low-country, has had the misfortune in harbouring the cheopis flea, in consequence of which plague was produced. Hattton is a town up-country where the cheopis is prevalent. Infection from Hattton also spread to Maskeliya. The enforcement of the anti-plague regulations is receiving more attention on the part of those concerned and towns are beginning to provide grain stores and approved rice bins for the storage of rice in addition to the enforcement of other requirements. The introduction of fresh infection from outside into Colombo is being dealt with by cyanide fumigation in barges of all grain and other merchandise liable to convey infection from plague-infected ports. The work commenced in September and is being efficiently carried out.

Diphtheria appears to be on the increase and a study is being made of its incidence.

Maternity and child welfare work continues to receive popular support. The number of centres at which work is carried out on approved lines, the number of clinics held and attendance at them, show a steady increase. The work was carried out at 77 centres, 4,543 clinics were held with a total attendance of 17,393 expectant mothers, 29,563 infants, and 18,611 pre-school children. The demand for more work cannot be adequately met for want of sufficient number of public health nurses. The conduct of this work in health units is beginning to show encouraging results in the diminution of infant maternal mortality.

School health work was carried out during the year with the full available staff. Two more medical officers were appointed during the year for school health work for the Panadura Totamune Health Unit and Matara Gravets and Wellaboda Pattin Health Unit. An additional trained public health nurse was appointed to the school medical officer of Galle. During the year 52,629 school children were medically examined, 73,757 defects were found in them and 21,979 were corrected. Provision has been made for dental treatment by nurses available to areas outside Colombo. The interest shown in school health education continues to be maintained through the initiative of medical officers of health and school medical officers. A special syllabus on health education, including practical work, was provided for teachers in training schools, the training of whom is undertaken by school medical officers and medical officers of health. The education department has undertaken the giving of a mid-day meal in schools in certain necessitous areas out of funds provided by the State Council.

The hookworm campaign made satisfactory progress during the year. Six additional qualified apothecaries were appointed as hookworm dispensers, in accordance with the policy to employ trained apothecaries in the place of hookworm dispensers. During the year a total of 1,885,572 treatments were given, as compared with 1,401,962 in 1935.

The leprosy survey has completed the Eastern, Western, and Southern Provinces and work has been organized in them.

Health work under Urban District Councils is carried out satisfactorily. Two of them continued to employ part-time private practitioners as their medical officers of health. The two Urban District Councils which had no medical officers of health at all have come into the scheme of health unit work which is in operation in the area surrounding the town. There is a tendency in one or two other Urban District Council areas to utilize the services of the medical officer of health in a purely advisory capacity in spite of the executive authority he has been granted by the Urban District Councils concerned. This is neither satisfactory nor in the interests of the areas concerned.

Health Unit work which is in operation in 11 areas has functioned satisfactorily. From its adoption for the malaria control scheme it is clear that the health unit type of work has received its well merited recognition.

ABSTRACT OF THE ANNUAL REPORT FOR 1935 OF THE PUBLIC HEALTH COMMISSIONER WITH THE GOVERNMENT OF INDIA

INTRODUCTION

In the general remarks in section I, the estimated population of India on 30th June, 1935, is given as 278,199,545. Births for the year totalled 9,698,794 and the deaths recorded came to 6,578,711.

The Public Health Commissioner states that the year under review was, if anything, less unhealthy than usual. This view is supported by the facts that the recorded births numbered 410,000 more than those of 1934, and the total deaths were less by 288,000.

There was a decrease of 24,000 in the total mortality from the three principal epidemic diseases—cholera, plague and smallpox. This decrease is largely accounted for by the reduction in plague deaths which fell from

80,000 in 1934 to 32,000 in 1935. The cholera mortality curve which has been rising since 1933 continued to rise during 1935, but the indications are that the present cholera wave has now passed its peak. There was an increase of 7,000 deaths in smallpox.

The report points out that regrettable though the extent of these major epidemics may be, there are still other diseases which cause much greater havoc although perhaps in a less dramatic way. Malaria, tuberculosis, leprosy, infant mortality and maternal mortality constitute grave dangers to public health. In all these five groups there exists a common predisposing aetiological factor which is of vital importance. This predisposing factor is nutrition. Its importance is stressed in the following terms:—

'No preventive campaign against malaria, against tuberculosis or against leprosy, no maternity relief or child welfare activities are likely to achieve any great success unless those responsible recognize the vital importance of this factor of defective nutrition and from the very start give it their most serious attention. Abundant supplies of quinine and the multiplication of tuberculosis hospitals, sanatoria, leprosy colonies and maternity and child welfare centres are no doubt desirable, if not essential, but none of these go to the root of the matter. The first essentials for the prevention of disease are a higher standard of health, a better physique and a greater power of resistance to infection. These can only be attained if the food of the people is such as will give all the physiological and nutritional requirements of the human frame. This question is obviously closely correlated with that of population and with the planning of sufficient and suitable food supplies. The question of numbers is the subject of later comment; that of food supplies is one of primary concern to the central and provincial agricultural departments and they may be expected to utilize available information on nutritional needs in planning food crops and food production. To obtain the best results, a close liaison must be maintained between the human nutritional research workers and those who can bring influence to bear on the food producer. Only when that liaison has been able to effect the quantitative and qualitative improvements in food supplies which research has shown to be so urgently necessary, will it be possible to anticipate any great or permanent reduction in the incidence of those diseases which at present take such a pitiful toll of human life in this country'.

POPULATION

The section devoted to population contains some startling figures. Apparently, at no period in the recorded history of Indian vital statistics has the natural increase of population maintained such a high level as in recent years and, in British India alone up to the middle of 1935, approximately 15 millions were added to the population since the last census was taken in 1931. Assuming that the same rate of increase has occurred in the Indian States, the population in India as a whole is stated to have increased since 1931 by 5 per cent bringing the total estimated number to well over 370 millions. The Professor of Vital Statistics and Epidemiology in the All-India Institute of Hygiene and Public Health, Calcutta, has recently published a paper entitled 'A Forecast of Population in India at the Census of 1941'. This forecast deals with a date only six years ahead so that it avoids the errors of a long term prediction. The birth rate in British India has been fairly steady from the beginning of the present century but the death rate has tended to decrease from 1921 onwards. Specific mortality rates were worked out for both males and females for the period 1921 to 1933, using estimated populations for each year, and it was found that the trend of mortality was downwards for all age groups except that of '60 years and upwards' in the case of both sexes. The conclusion drawn is that the fall in mortality recorded in recent years is real and that the death rate is unlikely to show an upward trend, at least in the near future. That being so, the application of further statistical analysis was justified and by two separate processes figures of approximately 402 and 400 millions respectively were obtained for the estimated

population of India as a whole in 1941. Provided, therefore, that the next five years keep free from abnormal epidemic or famine conditions, the population of India in 1941 is likely to approximate to 400 millions.

INFANTILE MORTALITY

The infantile mortality rate has shown a distinctly downward trend during the past two decades. Although some considerable reductions have been recorded in certain provinces in 1935, the report emphasizes that the infant death rates recorded in India are still pitifully high. A helpful analysis is made of the deaths under one year and it transpires that 40 per cent of these occurred in the first month. Of the deaths in the first month, 61 per cent occurred in the first week. Of the total deaths in India 43 per cent were among children under five years of age. These figures go to show the extreme necessity of developing in India an organization which will care for the health of the children and the mothers. An attempt has been made in recent years in Bombay city accurately to diagnose the different causes of infantile mortality. Debility and respiratory diseases account for 76 per cent of these deaths.

PRINCIPAL DISEASES

Section II of the report gives an account of the principal diseases affecting India. The only figures available for these diseases are those of recorded deaths which are admittedly defective. While in such circumstances it is ordinarily unsafe to make definite inferences from the statistics of any one year, the report nevertheless asserts that, on the assumption that the percentage of error is fairly constant, statistics over a period of years may reasonably be expected to give not unduly distorted epidemiological pictures. Under the varied headings of 'Fever' a death rate of 14 per mille was recorded. Similarly, the uninformative title of 'Other Causes' accounts for a death rate as high as six per mille. The importance of more accurate information does not require to be stressed. Even a partial exposition of the omnibus groups would almost certainly reveal problems demanding urgent attention. For example, such analyses would give public health departments much needed information on the real incidence of diseases such as pulmonary tuberculosis and enteric fever. In the absence of such epidemiological facts, the health officer is severely handicapped in his efforts to apply preventive methods. Until a general effort in these directions is practised, the epidemiologist using existing statistics may be accused with some degree of truth of mere speculation.

CHOLERA

In most of the provinces in which cholera was prevalent in 1935, its spread is ascribed in a majority of cases to the holding of fairs or festivals. The belated reporting of outbreaks facilitates the extension of the disease. The application of preventive methods lies entirely in the hands of the local authorities, and it is rightly emphasized that until district boards and municipal councils provide themselves with qualified health officers and adequate health staff, and until these bodies are prepared to spend money on efficient water supplies and sanitation, any campaign devised against cholera will almost inevitably prove abortive.

In the year under review, exceptionally severe epidemics of cholera prevailed in the provinces of Bihar and Orissa, Bengal, Central Provinces, Madras and Burma. Routine sanitary measures such as disinfection of water supplies, improved conservancy, inspection of pilgrims, etc., were carried out with varying degrees of efficiency. Inoculation with cholera vaccine is once more stated to be the most effective method of personal prophylaxis. Bacteriophage was tried in Assam, but the results are stated to have been inconclusive. It was also used in Bihar and Orissa. In Madras Presidency, its use was discontinued as the results obtained were not encouraging.

PLAGUE

It is heartening to read that plague does not now present the serious problem which it did in the earlier

years of the pandemic which has prevailed since 1896. Local outbreaks of some severity still occur and in certain restricted areas the disease occurs in endemic fashion. Figures given in the report indicate that up to 1918 plague took an annual toll of half a million lives. Between the years 1931 to 1934, this annual death roll has dropped to 50,000, and in the year 1935 plague mortality dropped to 32,000. This improvement cannot be attributed, at least in rural areas, to any permanent improvement in sanitary standards, and the suggestion is put forward that the lesser incidence of the disease in man may be the result of an increased immunity to the disease amongst the rats. Field research in anti-plague measures was carried out in the Cumbum Valley in Madras Presidency and the results illustrate the value of fumigation of rat burrows by means of cyanogas.

SMALLPOX

Deaths from smallpox rose to 280,881 as against 261,242 in 1934. This is all the more regrettable since, of all the major epidemic diseases, smallpox can be most easily prevented by the practice of vaccination. Each year eight to ten million persons submit to primary vaccination. An additional twelve to fifteen millions are revaccinated and many thousands acquire a natural immunity through an attack of smallpox. These three groups give the total number of persons protected each year, but when compared with the total population they comprise a small percentage only. There seems to be no doubt that vaccination in India can only be described as unsatisfactory. In many of the provinces, the health organizations are defective and the supervision of vaccinators, particularly in rural areas, is either non-existent or is performed in a perfunctory manner. For the same reason, outbreaks of the disease are not promptly reported to the health authorities and infection becomes widespread before necessary preventive action can be taken. Where satisfactory health organizations exist, satisfactory results have generally been obtained. Of the total deaths, fifty per cent were among children under ten years of age. In this connection the report points out the desirability of employing female vaccinators for vaccination work among women and children.

Of the 9,698,794 registered infants only 45 per cent were successfully vaccinated, and the report points out that this low percentage gives a clear indication of the generally backward state of protection in this country. The figures for vaccination staffs in the various provinces give the impression that the personnel employed is insufficient. More unsatisfactory than this, however, is the fact that the work of the vaccinators employed is inadequately supervised. This is clear from the opinions expressed by a number of Directors of Public Health that the average number of vaccinations performed by the vaccinators is inadequate. Obviously, supervision is lacking and this seems to be especially the case in rural areas.

Revaccination amongst women who observe strict purdah is stated to be a difficult problem. The employment of women vaccinators is the obvious way in which to remedy this.

(To be continued.)

Correspondence

GREASING THE SCALP IN HYPERPYREXIA

To the Editor, *The Indian Medical Gazette*

SIR,—The queries by a reader in the *Practitioner* of August 1937, and the answer by the editor about 'greasing the scalp in hay fever', have induced me to write this letter.

Greasing the scalp with ghee and the soles of the feet and palms of the hands with butter and oil is part of a routine domestic treatment among Indians for a headache in hyperpyrexia.

For greasing the scalp, generally ghee or oil only is used, and is rubbed in continuously for about 20 minutes. For greasing the palms of the hands and soles of the feet, ghee, butter, or oil may be used. These substances are rubbed with the aid of a *kansa valka*, a zinc utensil, until the grease is of a dark colour and is now called *kal*.

In the absence of knowledge about its rational action, it is not possible to say much about it, but to speak empirically it is quite certain that it is most efficacious in allaying a headache and the burning sensation of the hands and feet, and it relieves the patient of his discomfort to a great extent. This, I think, might be due to excretion of lactic acid produced in excess by muscular fatigue.—your, etc.,

SHANKERPRASAD K. SHUKLA,
Medical Officer.

BABRA DISPENSARY,
W. I. S. AGENCY
(KATHIAWAR).
21st October, 1937.

Service Notes

APPOINTMENTS AND TRANSFERS

The undermentioned are appointed Hon. Surgeons to the King

Colonel S. G. S. Haughton, C.I.E., O.B.E. Dated 10th August, 1937, *vice* Major-General E. A. Walker, C.B., retired.

Colonel N. M. Wilson, O.B.E. Dated 16th September, 1937, *vice* Major-General Sir Frank P. O'Connor, Kt., D.S.O., retired.

The dates of the appointment of the undermentioned officers to the Civil Branch of the Indian Medical Service are shown against their names:—

Major-General H. C. Buckley. Dated 20th April, 1920.

Colonel J. Taylor. Dated 4th October, 1913.

Lieutenant-Colonel R. E. Wright. Dated 14th February, 1914.

Lieutenant-Colonel A. N. Palit. Dated 24th October, 1922.

Lieutenant-Colonel K. G. Pandalai. Dated 24th April, 1922.

Lieutenant-Colonel F. R. Thornton. Dated 18th February, 1925.

Lieutenant-Colonel E. C. A. Smith. Dated 8th August, 1929.

Lieutenant-Colonel O. R. Unger. Dated 9th March, 1937.

Lieutenant-Colonel R. M. Kharegat. Dated 28th July, 1927.

Lieutenant-Colonel D. Clyde. Dated 13th February, 1924.

Lieutenant-Colonel R. C. Clifford. Dated 1st July, 1930.

Lieutenant-Colonel R. L. Vance. Dated 29th April, 1931.

Lieutenant-Colonel H. Williamson, O.B.E. Dated 28th August, 1932.

On return from leave Lieutenant-Colonel C. J. Lodge-Patch, M.C., resumed charge of the office of Medical Superintendent, Punjab Mental Hospital, Lahore, on the 27th January, 1938.

Lieutenant-Colonel J. R. Kochhar appointed as Specialist in Radiology, Lahore District.

The services of Lieutenant-Colonel B. Gale, Civil Surgeon, Simla-E., were replaced at the disposal of the Government of Punjab. Dated 29th October, 1937.

On return from leave Lieutenant-Colonel P. D. Chopra assumed charge of the office of Superintendent, New Central Jail, Multan, on the 11th January, 1938.

The undermentioned officers are reverted to Military duty.

Lieutenant-Colonel C. S. V. Ramanan on 6th November, 1937.

Lieutenant-Colonel R. A. Logan, on 21st November, 1937.

Lieutenant-Colonel R. L. Vance, on 12th November, 1937.

Major H. M. Strickland, on 10th November, 1937.

The following officers have been appointed to the Civil Branch of the I. M. S. with effect from the 1st April, 1937, with seniority from the dates noted against each :—

Major D. P. Lambert. Dated 13th June, 1934.

Major E. S. S. Lucas. Dated 30th October, 1934.

Major R. A. Wesson. Dated 16th November, 1934.

Major C. K. Lakshmanan is appointed provisionally as Port Health Officer, Calcutta, with effect from the 21st October, 1937 (afternoon), until further orders.

Major B. N. Hazara made over charge of the Barisal Jail to Dr. Monoj Nath Gupta, in the afternoon of the 30th November, 1937, and the latter made over charge of that jail to the former in the forenoon of the 6th December, 1937.

Major R. L. Frost appointed as Civil Surgeon, Myingyan, dated 16th January, 1938.

The undermentioned officers are appointed to the Civil Branch of the Indian Medical Service with effect from the 1st April, 1937. These officers will count their seniority in civil employment with effect from the dates noted against their names.

Lieutenant-Colonel C. M. Nicol. Dated 10th December, 1934.

Major D. P. Lambert. Dated 13th June, 1934.

Major R. A. Wesson. Dated 16th November, 1934.

Captain P. J. Kelly. Dated 8th July, 1934.

Captain H. S. Smithwick. Dated 29th October, 1934.

Captain E. S. S. Lucas. Dated 30th October, 1934.

Captain P. L. O'Neill. Dated 10th November, 1934.

Captain Sangham Lal. Dated 14th November, 1934.

The undermentioned I. M. S. Officers were transferred to civil employment :—

Captain J. Brebner, on 28th December, 1937, on transfer to civil Bengal.

Captain W. Happer, on 24th December, 1937, on transfer to civil Punjab.

Captain B. J. Griffiths, on 10th January, 1938, on transfer to civil U. P.

Captain W. P. Lappin, on 20th January, 1938, on transfer to civil Madras.

Captain W. McN. Niblock, on 7th January, 1938, on transfer to civil Bengal.

Captain D. Tennant, on 20th January, 1938, on transfer to civil Assam.

Captain F. A. B. Sheppard, acting District Medical Officer, East Godavari, and Superintendent, Government Headquarters Hospital, Cocanada, to act as District Medical Officer, Madras, and Superintendent, Government Headquarters Hospital and Medical Officer, District Jail, Madura, with effect from the date of taking charge, vice M. R. Ry. Rao Bahadur S. Padmanabha Sarma Avargal.

Captain W. P. Lappin on transfer from the Military Department, to act as Junior Specialist in Surgery in the Medical College and the King George Hospital, Vizagapatnam, with effect from the date of his report to civil duty.

Captain C. F. Garfit, whose services have been placed at the disposal of the Punjab Government against the leave reserve for European Officers of the Indian Medical Service, was placed on general duty at the Mayo Hospital, Lahore, with effect from the 27th January, 1938.

Captain C. B. Miller has been reposted as Resident Medical Officer, J. J. Hospital, Bombay, with effect from the 10th January, 1938, afternoon.

Services of Captain B. J. Griffiths have been transferred to U. P. with effect from 12th January, 1938.

Captain M. H. Shah is appointed as a leave reserve Officer from 16th October, 1937, and is posted to the Province of Delhi for employment, until further orders, at the Willingdon and Irwin Hospitals.

Captain W. Happer, on transfer from the Military Department to Madras Civil, to act as District Medical Officer, Guntur, and Superintendent, Government Headquarters Hospital, Guntur, with effect from the date of taking charge.

Captain J. Brebner, on arrival in Bengal, is placed on general duty at the Medical College Hospitals, Calcutta.

To be Captain (on prob.)

W. S. Davidson. Dated 1st November, 1937, with seniority as Lieutenant, 22nd October, 1933, and as Captain, 22nd October, 1934 (Secd.).

To be Lieutenant (on prob.)

1st November, 1937.

G. K. Beatty (Secd.).

C. W. Greene (Secd.).

G. A. Graham (Secd.).

The following officers arrived at Bombay on first appointment on 6th January, 1938 :—

Lieutenant W. A. Hopkins.

Lieutenant J. L. Mewton.

Lieutenant L. U. Kamm.

Lieutenant T. Denness.

Lieutenant J. W. R. Sarkies.

LEAVE

Lieutenant-Colonel F. Griffith proceeded on 12 months' leave ex-India, pending retirement, from 14th January, 1938.

Lieutenant A. G. Goode proceeded on 2 months' leave ex-India, pending resignation, from 18th January, 1938.

Lieutenant-Colonel Som Dutt proceeded on 2 months' leave in-India, pending retirement, from 28th January, 1938.

Lieutenant-Colonel D. R. Thomas, o.b.e., Chemical Examiner to Government, Punjab, proceeded on combined leave for nine months, with effect from the 25th January, 1938.

Lieutenant-Colonel P. Verdon, Acting Superintendent, Government Ophthalmic Hospital, Madras, and Professor of Ophthalmology, Medical College, Madras, has been granted leave ex-India for two months and sixteen days on average pay and for six months and fourteen days on half average pay, with effect from the 15th February, 1938, or the date of relief.

Major H. W. Mulligan, Assistant Director, Malaria Survey of India, on foreign service under the Indian Research Fund Association, granted leave on average pay ex-India for eight months, with effect from the afternoon of the 16th December, 1937. His services are replaced at the disposal of the Director-General, Indian Medical Service, from that date.

PROMOTION

Colonels to be Major-Generals

N. M. Wilson. Dated 16th September, 1937.

P. S. Mills, c.i.e. Dated 16th November, 1937.

Lieutenant-Colonels to be Colonels

G. G. Jolly, c.i.e. Dated 16th November, 1937, with seniority from 1st February, 1932.

H. Stott, o.b.e. Dated 16th November, 1937, with seniority from 1st February, 1932.

E. S. Phipson, c.i.e., d.s.o. Dated 1st December, 1937, with seniority from 1st February, 1932.

J. Scott, d.s.o., o.b.e. Dated 9th July, 1937, with seniority from 1st July, 1931. This promotion does not carry with it the benefits of pay and pension admissible to officers of this rank, until such time as he assumes an administrative appointment permanently.

Lieutenant-Colonel to be Brevet-Colonel

Lieutenant-Colonel J. W. Vanreenen, o.b.e. Dated 1st January, 1938.

Majors to be Lieutenant-Colonels

J. W. F. Albuquerque. Dated 22nd December, 1937.
 Major C. V. D. Rose, promotion to present rank of Major is antedated to the 25th April, 1931.
 Major C. Mani, promotion to present rank of Major is antedated to 1st April, 1937, with seniority in that rank from 19th February, 1937.

The promotion of the following officers to the rank of Major notified is antedated as noted below :—

W. F. Cooper. Dated 1st April, 1937, with seniority in that rank from 2nd November, 1936.

A. K. M. Khan. Dated 1st April, 1937, with seniority in that rank from 15th January, 1937.

B. Chaudhuri. Dated 1st April, 1937, with seniority in that rank from 2nd February, 1937.

Captains to be Majors

Captain P. P. Chowdry, I.M.S. Dated 22nd November, 1937.

E. A. R. Ardeshir. Dated 16th December, 1937.

Lieutenants (on prob.) to be Captains (on prob.)

B. J. Doran. Dated 8th November, 1937, with seniority from 31st October, 1937.

J. H. Cater. Dated 31st October, 1937.
 S. Shone. Dated 15th October, 1937, with seniority from 1st November, 1936.

G. W. Palmer. Dated 19th October, 1937, with seniority from 1st May, 1937.

G. F. J. Thomas. Dated 8th November, 1937, with seniority from 13th October, 1937.

Promotion and antedates

The seniority of Lieutenant W. A. Hopkins is antedated to 31st August, 1936.

RETIREMENTS

Major-General D. P. Gail. Dated 16th November, 1937.

Colonel C. E. Palmer. Dated 1st December, 1937.

Lieutenant-Colonel C. Newton-Davies, M.C. Dated 18th December, 1937.

RELINQUISHMENT

Captain J. A. L. McCullough relinquishes his probationary appointment. Dated 7th October, 1937.

Notes

ACIDOSIS AND KETOSIS

Aemosis and ketosis occur in cases of starvation, obstinate vomiting, such as pernicious vomiting of pregnancy, debility in children, cyclical vomiting, delayed anaesthetic poisoning, and in pyrexial conditions; also (especially acidosis) in cases of nephritis and of poisoning by salicylates or by ammonium chloride. Ketosis also occurs frequently in diabetes, but from a different cause. The symptoms vary with the severity of the case, and may include air-hunger, sickness, drowsiness, irritability, depression, restlessness, night terrors, vomiting and, in severe cases, coma.

Treatment consists of introducing alkalis and dextrose into the patient's system. There are several ways of doing this. Bicarbonate of soda in drachm doses, dissolved in water to which lemon juice and one ounce of dextrose have been added, may be given every three hours. In more severe cases, one pint of a 10 per cent solution of dextrose and a 5 per cent solution of bicarbonate of soda may be given per rectum. In extremely severe cases, a 2.5 per cent solution of dextrose in a 5 per cent solution of sodium bicarbonate may be given intravenously. These solutions should be freshly prepared. For people who are liable to periodic attacks of ketosis, dextrose is an excellent prophylactic.

Dextrosol brand dextrose is primarily the physician's glucose. That is to say, only the most reasonable and thoroughly attested claims are made on behalf of this product, and it is not advertised to the general public—its sales are promoted only by the recommendations of physicians.

Dextrosol is obtainable from Messrs. Corn Products Company (India), Limited, Post Box No. 2191, Calcutta, India.

PROSEPTASINE AND SOLUSEPTASINE

In the field of chemotherapeutic research a vast amount of work has been undertaken in attempts to discover a chemical substance capable of destroying the streptococcus in a manner comparable to that in which the arsphenamines deal with the *Spirochaeta pallida*. The products of these labours, however, were of little practical value until in 1935 Domagk announced the remarkable power possessed by the red dye, 4'-sulphamido-2:4-diaminoazobenzol, of protecting mice against infection with virulent strains of haemolytic streptococci.

A water-soluble form was later introduced for intramuscular injection, and originally also for intravenous use: but both these preparations have the disadvantage of being dye-stuffs.

Other workers discovered that their streptococcicidal activity is attributable, not to the azo dye, but to the benzene-sulphonamide portion of the molecule.

Early in 1936 Pharmaceutical Specialities (May and Baker) Ltd. were the first to introduce to the medical profession in Britain a colourless antistreptococcal drug for oral administration. That product, Proseptasine, is a derivative of *p*-aminobenzene-sulphonamide, and its toxicity is considerably less than that of the original dye product, although its curative activity is at least as good. Subsequently *p*-aminobenzene-sulphonamide, also known as sulphanilamide, was introduced, but experimentally Proseptasine has been shown to be even less toxic than this simple sulphonamide.

Following on further research and clinical trials, Soluseptasine, which is a colourless drug for intravenous administration, which may also, if desired, be given by subcutaneous or intramuscular injection, was introduced.

In the experimental streptococcaemia of the mouse, Proseptasine has a remarkable action. A highly virulent strain of streptococcus is used, and the animals employed in the test are infected with a uniform quantity of the virus. The quantity administered is usually one hundred times that which would normally prove lethal within 48 hours. The animals to which no protective dose of proseptasine has been given invariably die within 48 hours. The other test animals are given a first dose of proseptasine from half to three-quarters of an hour after the initial infection. Further doses are given on subsequent days. Comparative tests have also been carried out with other products, and it has been found that the infected animals usually survive for a longer period when treated with Proseptasine.

Soluseptasine is, like Proseptasine, a complex sulphonamide, but differs from the latter in being readily soluble in water.

There are certain urgent cases in which a therapeutic advantage may be gained by giving a drug intravenously, and Soluseptasine may be so administered with no more risk of toxic reaction than when introduced by the subcutaneous or intramuscular route. Clinical trials confirm both the streptococcicidal activity and the low toxicity of this product.

SARDANA'S MODIFIED VACCINATION LANCET

THIS instrument is a modification of Weir's scarificator. It consists of round hollow metallic handle 4 inches long and $\frac{3}{4}$ inch in circumference. On one end of this handle is screwed a metallic plate which has four scarificating points set $\frac{1}{16}$ inch apart, each about $\frac{1}{2}$ inch long. On the other end is screwed a narrow spatula nearly $1\frac{1}{2}$ inches long with maximum width $\frac{3}{16}$ inch at the distal end. Both these metallic pieces, the one carrying the points and the other carrying the spatula, can be reversed and screwed in such a way that they go into the hollow of the handle when not in use. The joints have been made leakproof so that the hollow of the handle can be used as container for an antiseptic lotion; the scarificator and the spatula are thus kept sterilized. The closed instrument is nearly $4\frac{1}{2}$ inches long and can be carried in an ordinary waistcoat pocket. The spatula is used for carrying lymph from the vial to the arm and rubbing it in after scarificating with the points.

The special advantage of the instrument over others is its compactness and the fact that the important parts are kept sterilized. This is of special significance for vaccinators who have to go from village to village and from field to field where facilities for quick sterilization of the instrument are scarce or non-existent.

The instrument has been manufactured by Messrs. Union Surgical and Company, Sialkot, Punjab.

M. N. SARDANA, Captain, A.I.R.O.,

M.B., B.S., L.R.C.P., M.R.C.S., D.O.M.S., F.R.F.P.S.
Chief Medical Officer, Bharatpur.

[Note.—The only criticism we have of this very ingenious instrument, which we have seen and used, is that there is nothing to keep the two washers that are not being used in position. This applies particularly when the instrument is closed. Some means of locking them on might be devised.—Editor, I.M.G.]

NEUTRAL ACRIFLAVINE

NEUTRAL ACRIFLAVINE—Boots (Euflavine—Boots) is a mixture of 2:8-diamino-10-methylacridinium chloride and 2:8-diaminoacridine hydrochloride. The presence of a sufficient proportion of the latter results in a more soluble product than the pure 2:8-diamino-10-methylacridinium chloride. It is an odourless brownish-red powder, soluble in water, slightly soluble in alcohol, nearly insoluble in ether, chloroform, fixed oils and liquid paraffin.

Indications

Neutral acriflavine—Boots, being a neutral product, is particularly indicated for either oral or parenteral administration, in preference to the more acid acriflavine.

Method of administration

Oral.—For oral administration neutral acriflavine is given in the form of enteric-coated tablets. The special enteric coating enables the tablets to pass through the stomach unchanged, thus avoiding gastric solution which might cause nausea; the tablets quickly disintegrate upon reaching the alkaline intestinal tract. Depending upon the degree of infection it is found that $\frac{1}{2}$ gr. to 1 gr. three times a day is usually effective. It is essential, however, to ensure marked alkalinity of the urine as the bactericidal properties of acridine antiseptics are enormously enhanced in an alkaline medium.

Urinary infections.—Infections of the kidney, whether a gross obstruction such as a calculus in the pelvis or ureter be present or not, probably cannot be

sterilized by any urinary antiseptic at present available. It is possible, however, in healthy men to procure unfailingly the secretion of urine antiseptic toward both *B. coli* and staphylococcus after the administration of acriflavine combined with alkalinization' (Davis and Sharpe, *Brit. Med. Journ.*, 1934, II, 581).

'I have recently had a very stubborn case of *B. coli* infection of the kidney and bladder, and have obtained two consecutive negative cultures at two months' intervals from the use of acriflavine. Messrs. Boots have made a tablet of this drug otherwise so inconvenient to administer, which my patient has been able to take regularly' (*Brit. Med. Journ.*, 1928, II, 553).

VERITOL

KNOLL, A-G., Ludwigshafen-on-Rhine, Germany, whose diuretic and cardiazol preparations have long been known for their valuable properties, have now brought out a new circulatory restorative, called 'Veritol (Knoll)', which possesses considerable advantages over adrenalin and ephedrine. Veritol is p-oxyphenyl-isopropyl-methylamine. Its action is slower yet more enduring than that of adrenalin, and unlike ephedrine, it exercises no injurious effects on the heart.

Veritol increases the volume of the circulating blood by emptying the blood depots; its action is, therefore, largely physiological. Samples for clinical trial are obtainable from Messrs. Martin and Harris, Limited, Mercantile Buildings, Lall Bazar, Calcutta.

Publishers' Notice.

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to '*The Indian Medical Gazette*', Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers (if available) for the previous year Rs. 2-8 each, and all other back numbers Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, nor creased, in transit.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

PRESENT POSITION OF THE OPIUM SMOKING HABIT IN INDIA

PART III

STUDIES ON THE PHYSICAL AND MENTAL EFFECTS PRODUCED BY OPIUM SMOKING. (AN ANALYTICAL REVIEW OF 300 OPIUM SMOKERS EXAMINED IN THE FIELD)

By R. N. CHOPRA, C.I.E., M.A., M.D., Sc.D. (Cantab.),
M.R.C.P. (Lond.)

BREVET-COLONEL, I.M.S.

Honorary Physician to the King
and

G. S. CHOPRA, M.B., B.S.

(Department of Pharmacology, School of Tropical
Medicine, Calcutta)*

In two previous communications the present authors have traced the history of the introduction of opium smoking into India and have described its incidence in different parts of the country. The method of preparing opium for smoking and the modes of indulgence, the types of persons addicted, and the control exercised by the state have been discussed. After a careful survey of the habit two aspects of the problem have presented themselves to us.

Firstly, that the literature and the available data with regard to the physical and mental effects produced by prolonged and habitual smoking of opium are meagre and of somewhat controversial nature.

Secondly, little attempt has been made so far to investigate the relationship between the two aspects of the opium problem, *i.e.*, eating and smoking.

We have paid attention to these aspects and have studied the bearing of climatic, racial and economic factors in connection with the causation of the habit. A series of 300 smokers were studied for prolonged periods by examination at frequent intervals. It is to be recorded that for want of proper laboratory facilities in the field many of the biochemical examinations could not be carried out.

ÆTIOLOGICAL FACTORS

(1) Predisposing causes

(1) *Social and environmental factors.*—A study of the conditions existing in the areas where the practice of smoking opium is common has convinced us that social and economic factors play an important part in starting and continuing this habit. The standard of social and hygienic conditions of the working classes in these areas is very low. No healthy amusements are available and the workers living under such conditions are in search of some form of

diversion which will enable them to forget, at least for the time being, the monotony, hardships and worries of their daily existence. Their intellectual development is low, the housing conditions are primitive, and overcrowding is general. The temptation and need for a euphoric is therefore always there. A large proportion of the addicts we have studied in the tea gardens and forest areas in Assam and the Central Provinces said that they took to opium smoking because they had to perform strenuous work in an unhealthy climate. They believed that opium had a general stimulant action and increased their vigour and working capacity, and kept off hunger and fatigue. This belief has been responsible for the spread of the habit amongst the labouring classes in some of the tea gardens and the forest areas.

(2) *Race.*—Among the Mongolian races there appears to be an instinctive desire for a stimulant, and drugs possessing euphoric properties appear to have more attraction on account of their pleasure-giving and probably supposed aphrodisiac properties. The racial factor is in all probability responsible for the higher incidence of opium smoking in Assam and Burma as compared with any other part of India. The high incidence in the Central Provinces is, however, difficult to explain.

(3) *Heredity and contact.*—A perusal of table I shows that 94 (or 31.3 per cent) of the addicts gave a history of addiction in some member or other of the family, while in the remaining 206 (or 68.6 per cent) no other member of the family smoked the drug. Further, it will be seen that in 44 cases (14.6 per cent) one or other of the parents was an addict. In 20 cases (6.6 per cent) real uncles and grandparents were also in the habit of smoking the drug. While in 30 (10.0 per cent) more than one relation was addicted to smoking. This table brings out that association and contact are factors to be considered, while heredity plays little or no part. We have met with instances where a small dose of opium was given to a child by the parent for some minor ailment for prolonged periods leading to habit formation, or to a wife by her husband, or to a younger member of the family by an elder, leading to similar results.

TABLE I

Showing the effects of heredity and contact in a series of 300 opium smokers studied

	Father	Uncle	Mother	Grandfather	More than one relative	None
Other relatives addicted.	40	10	4	10	30	206
Percentage ..	13.3	3.3	1.3	3.3	10.0	68.6

* This work was commenced under a grant from the Indian Research Fund Association and during the last year has been carried on under the Endowment Fund of the Calcutta School of Tropical Medicine.

We have also heard that in former days it was customary for parents to encourage their offspring and for wives to induce their husbands to smoke opium in order to avoid their indulgence in dissipation of other kinds.

(4) *Age to contract the habit.*—A large percentage of this series, that is, 225 or 75.0 per cent, started the habit at an early age, that is, between the ages of 10 and 30 years, which is the period when the individual is particularly susceptible to any sensations of an extraordinary nature, especially those pertaining to euphoria and sex. This is the dangerous period of life and contact with other smokers at this time is liable to start the habit. A perusal of table II illustrates that in 103 cases (34.3 per cent) the habit of smoking was acquired below the age of 20 years. In 122 (40.6 per cent) it was begun between the ages of 21 and 30 years. These two groups consist of young adults in whom euphoric factors and contact are important exciting causes. In both these groups there was a tendency to drift to larger doses, that is, more than 20 grains a day. In 42 (14.0 per cent) the habit developed in early middle age, that is, between 31 and 40 years, while in the remaining 33 (11.0 per cent) cases it was picked up after middle age, that is, after 40 years of age. In persons who started smoking in middle age and after, disease and hard work were important exciting causes in contradistinction to euphoria and the sexual factor which were mainly responsible at the early age.

TABLE II

Statement showing ages to contract the habit in a series of 300 opium smokers studied

	20 years and under	21 to 30 years	31 to 40 years	41 years and over	Total
Number	103	122	42	33	300
Percentage	34.3	40.6	14.0	11.0	100

(5) *Present ages of opium smokers.*—As a rule opium smokers have no idea of their age. A youth of 20 would state that he was 50 years of age and a man of 40 would say that he was 20 years old. The smokers often calculate their ages from some important event or events in their lives, the exact dates of birth being forgotten. In table III we have given the approximate ages estimated from the physical examination of the addicts.

None of the addicts in our series of 300 cases was below 12 years of age and only 2 per cent were below 20 years. This shows that at the present time the habit is not being contracted by youngsters as was the case 30 years ago. Most of the addicts seen were between 35 and 60 years of age, there being only one above 70

TABLE III

Showing the present ages of addicts in our series of 300 cases studied

	Number of cases	Percentage
Between 12 and 20 years	6	2
" 21 and 30 "	26	8.6
" 31 and 40 "	40	13.3
" 41 and 50 "	98	32.6
" 51 and 60 "	105	35.0
" 61 and 70 "	24	8.0
" 71 and 80 "	1	0.3
	300

years. This may be due to the fact that smokers' lives are short, and they generally succumb to some intercurrent diseases and die before attaining a ripe old age.

(2) *Exciting causes*

(1) *Association, pleasure and euphoria.*—A perusal of table IV will show that in this series there are 150 persons (50 per cent) who are pleasure seekers and who smoked the drug entirely for its euphoric effects. They were mostly young persons who had little to do, were ease-loving and spent most of their time in enjoyment and recreations peculiar to their class (e.g., chess, dice, cock fighting, etc.). These persons started the habit because of their association with others who indulged in similar amusements and who were smokers.

In Assam, the Central Provinces and Berar, large sections of labourers in forest areas and tea estates are housed together. The opium smokers amongst them often try to tempt the non-smokers to smoke the drug. Others learn to smoke in clandestine smoking dens which are run by the traffickers in this drug.

The opium smoker should be regarded as an individual who acts as a focus of infection for susceptible individuals. In India ordinarily it is difficult to obtain prepared opium for smoking purposes, but once the acquaintance with habitual smokers is developed, ways and means of securing these preparations are found. The addicts, as a rule, do not reveal the names of the manufacturers and distributors of these preparations. When the habit is confirmed, the new consumer realizes his helplessness especially if he has had the misfortune of running short of the drug and experiencing the symptoms of sudden withdrawal. Very often he himself starts manufacturing these preparations and keeps a supply in hand in case of emergency. A smoker may have no money for his daily food, may be insufficiently clad, yet will manage to get his dope, as this is the only method of escape from the acute mental and physical sufferings produced during the period of abstinence. He will pawn or sell his personal belongings and those of his family and will try to get the drug

even if he has to sacrifice all that he possesses in the world. The ravages caused by the habit in such persons are terrible and the moral depravity produced is indescribable.

TABLE IV

Showing the factors which were directly responsible for the opium smoking habit in a series of 300 addicts studied

	Number of cases	Percentage
1. Association, pleasure, euphoria, etc.	150	50
2. Disease	100	33.3
3. Hard work, fatigue, etc.	40	13.3
4. Substitute for other drug habit.	10	3.3

2. Disease.—Sufferings produced by disease conditions are very commonly blamed for producing drug addiction. The rôle of the disease factor was studied in detail in this series. It will be seen from a perusal of table IV that in 100 (33.3 per cent) this factor acted as an exciting cause. In a hot humid climate, such as is met with in Assam, where the incidence of cough, asthma, dysentery, typhoid, malaria, kala-azar and bowel infections is high, there is a widespread belief that the regular use of opium, whether by smoking or eating, acts as a prophylactic against, and also as a cure for, these diseases. On account of the power this drug possesses of depressing the respiratory centre the irritative cough is ameliorated. The effects upon the gastro-intestinal tract, particularly in diarrhoea and dysentery and painful affections, are known to be rapid and very striking. These 100 cases were further analysed as to the nature of the ailment or affection which led to the use of the drug and the results are given in table V :—

TABLE V

Statement showing various diseases for which 100 addicts started opium smoking

Diseases	Percentage
1. Aches, pains and other rheumatic troubles	25
2. Cold and cough, coryza	14
3. Hæmoptysis	8
4. Asthma	12
5. Pulmonary tuberculosis	5
6. Bowel diseases (dysentery, diarrhoea, etc.)	7
7. Sciatica	4
8. Piles	2
9. Need of a general tonic	6
10. Palpitation of the heart	2
11. Spermatorrhœa	2
12. Fevers (malarial and kala-azar in origin)	10
13. Gonorrhœa	1
14. Syphilis	1
15. Enlarged spleen	1
	100

It will be observed that diseases of the respiratory system, such as cold, cough, coryza, asthma, hæmoptysis, etc., are common amongst the exciting causes. Then come aches, pains such as sciatica, neuralgia and rheumatic troubles, and then follows its use in fevers and as a general tonic and for bowel diseases. In all these instances the use of the drug was often started by suggestion at the instance of a smoker and in no case was it begun on the advice of a qualified medical practitioner.

(3) *Fatigue and hard work.*—Only in 40 cases (13.3 per cent) was the habit started to enable the addict to bear the strain and stress of hard work.

(4) *As a substitute for alcohol and other drug habits.*—A glance at table IV will show that 10 addicts (3.3 per cent) in this series took to opium smoking as a substitute for such drug habits as alcohol and cocaine. These addicts stated that a few whiffs of opium satisfied their cravings for cocaine and alcohol, and therefore the desire for these drugs was minimized with comparatively smaller doses of opium smoking. All these ten individuals were weaklings of vicious temperament who were given to multiple drug habits and excessive drinking. The reason for substituting opium smoking often was that they found it less expensive than cocaine or alcohol.

SYMPTOMATOLOGY

From the description already given it is evident that the two preparations of opium used for smoking, *madak* and *chandū*, vary a great deal in their potency. Most of the Indian smokers indulge in *madak* which is considerably less potent, while *chandū*, the stronger preparation, is smoked by very few, but particularly by those who are addicted to large doses of the drug and in whom marked tolerance has developed. The symptoms produced in both groups are very much alike.

The following description of symptoms produced by smoking of opium in Indian smokers has been compiled from the description given by habitual smokers themselves. We were able to divide the smokers into four groups. Practically every individual passed through all the four stages unless he gave up the habit early.

I. *New habitues.*—In persons who have just started smoking opium, the symptoms produced are those of euphoria. At the onset the senses become momentarily keen; the stimulant effects are produced by the first pull; physical pains of whatever nature disappear or become abated; there is a feeling of elation, followed by a delightful languid ease, exalted sense of superiority, and later on sleep with pleasant dreams. As smoking progresses the smoker becomes dull and drowsy. If at this time he receives some important and exciting news, he takes little notice of it and indulges in another smoke. Soon after he has finished the first pipe

the smoker becomes talkative and communicative. He talks of politics, religion, poetry, and other subjects of special interest to himself. The facts are often exaggerated and he is overconfident of his powers and superiority. He mostly talks of his personal affairs and thinks that he is logical in all his expressions and conclusions. He is disposed to criticize others and is anxious to prove all sorts of fantastic theories in order to impress his hearers (who are generally smokers themselves) and who listen attentively. Time is of little consequence. The smoker becomes a slave to the habit and the evil is enhanced by the bad surroundings in which the habit is generally indulged in.

II. *Early stages of addiction.*—As the habit takes root the individuals gradually become conscious of the danger and ill effects of the practice. Attempts and efforts are often made to give up the habit and a constant struggle seems to be going on between his sense of caution on the one hand and his desire for euphoria on the other. The symptoms produced are similar to those produced in the first group, but are less marked. There is a general attitude of hesitation during this period and the habit is continued partly because of its pleasure-giving effects and partly because of the dread of the abstinence symptoms.

III. *The stage when the habit is established.*—Prolonged use of the drug is apt to produce permanent changes in the system. The mental and moral faculties are affected and the addict behaves more or less like an abnormal individual. After the drug is smoked the symptoms of incompetency and inhibition present during the abstinence period completely disappear. The drug, however, is able to produce only a temporary sense of well-being, and no marked euphoria or intoxication, as is seen in the first two stages. Addicts at this stage have a desire to give up the habit, but are unable to do so on account of the dread of the withdrawal symptoms.

IV. *Stage of long-standing addiction.*—The old habitués if they do not change their mode of consumption are apt to get into a stage of cachexia or inanition. The mental and physical changes are much more marked in this group than in the previous three groups. The physical changes may go on to actual dementia. The individual is pale, thin and is subject to all intercurrent diseases. The craving for the drug is greater than ever. When the drug is smoked by such individuals the euphoric symptoms are absent. The only effect produced is a short-lived feeling of normality after indulging in a smoke. The feeling of constant and general depression always present is overcome for the time being. If smoking cannot be indulged in at the proper time there is great prostration, vertigo, torpor, discharge of water from the eyes, acute distress and insomnia. All these feelings are overcome for the time being by the smoking of a single pipe of opium.

Withdrawal

Most opium smokers smoke the drug because of the very distressing symptoms which are produced if they do not smoke it. Prolonged indulgence often fails to give pleasurable sensations, yet he must go on smoking in order to avert the crisis of withdrawal symptoms. The horror of pain both mental and physical is an obsession which the smoker dreads. The abstinence or withdrawal symptoms in case of opium eating and smoking are the same, there being a question of degree. As a rule the symptoms set in more rapidly and are more intense in smokers than in eaters. The early symptoms are yawning, sneezing, nausea, vomiting, and mucous secretion resulting from stimulation of the medulla; abdominal pains and diarrhoea occur from stimulation of Auerbach's plexuses; the twitchings, cramps, circulatory troubles (rapid pulse, arrhythmia), and sometimes convulsions and collapses are due to excessive stimulation of the cortical cells. A chilly sensation is felt all over the body and there are general aches and pains. Sometimes there is a peculiar dull, drawing, dry and burning sensation in the region of the pharynx and larynx which may be followed by severe pains in the shoulders and muscles of the calves and thighs. In some there is involuntary discharge of semen even when widely awake. A patient seen with these symptoms, even when in a state of collapse, after a few pulls at the pipe exhibits a transformation almost miraculous; he becomes in a few minutes a relatively normal person.

Whatever peculiar characteristic of mind or accidental incidents may determine the formation of the habit, when once it is formed the patient has a real disease, and he can only exist free from great physical and mental pain when he is under the influence of the drug. Thus the symptoms of abstinence vary from an initial anxiety and uneasiness and a feeling of weakness to a state of severe shock, which in feeble persons may have serious consequences. If opium is administered the symptoms quickly disappear and if the addict is too weak to inhale, opium smoke is blown into his nostrils. It is said that if the mother is an addict, her child may have to be revived from time to time in the same way. Though the dose has to be continually increased, the craving never reaches such a great intensity as in those who take morphine by injection. This is probably due to the fact that the amount of morphine actually absorbed from the smoke is very small.

AN ANALYSIS OF THE PHYSICAL EFFECTS AS OBSERVED IN A SERIES OF 300 OPIUM SMOKERS

In a previous paper (1935) the present authors gave the results of their comprehensive studies regarding the physical and mental effects produced by opium eating in this country.

The question with regard to effects produced by opium smoking was left for a further study. The lines of investigation followed in this series of 300 opium smokers were the same as with opium eaters.

General appearances.—The addicts in this series were mostly labourers working on the tea estates in the Assam valley. Contrary to what may be expected of people leading an open-air life, the majority of these workers did not look healthy, even at their best. It is not surprising therefore that the majority of the smokers examined were found to have poor physique, had flabby musculature and defective posture, and looked cheerless and morose. Out of 300 smokers examined 270 (90 per cent) were males and 30 (10 per cent) were females. They had a pale, sallow countenance, wrinkled face, eyes devoid of lustre and looked altogether miserable specimens of humanity.

Height and chest measurements and body-weight.—Unlike opium eaters (Chopra and Chopra, 1935) their height and chest measurements were below the standard.

The effect of opium smoking on the body-weight was carefully studied and compared with that of a series of opium eaters of the same locality.

It was found that opium, when it is smoked in small doses (5 to 6 grains daily), affects the weight to a lesser extent than when it is eaten. In those who smoke more than 10 grains a day, the effects of opium smoking on the body-weight appear to be more pronounced than opium eating. For example, in individuals who smoked more than 20 grains a day, the shortage of weight per individual was as much as 25 lb. against 17 lb. in the case of opium eaters as compared with the average of non-addicts.

TABLE VI

Showing effects of opium smoking on body-weight as studied in a series of 300 opium smokers

Doses	AVERAGE LOSS IN WEIGHT PER INDIVIDUAL IN POUNDS	
	Opium smokers	Opium eaters
5 grains and under ..	14.5 lb.	15.8 lb.
6 to 10 grains ..	15.5 "	15.9 "
11 to 20 grains ..	18.8 "	18.8 "
21 grains and over ..	25.0 "	17.0 "

Respiratory system.—The incidence of diseases of the respiratory system appears to be very high. Thus 146 or 48.6 per cent suffered from one ailment or other of the respiratory tract (table VII). It may be observed that most of the habitués were weak, emaciated, lived in mud huts thatched with grass which were damp and badly ventilated, and were usually overcrowded at night. These individuals, therefore, fell an easy victim to respiratory troubles. Five cases in this series suffered from dry pleurisy and 15 from pulmonary tuberculosis. Among quite a large number of opium smokers the type of respiration even in male adults is more of the abdominal than of the thoracic type and the amount of tidal air is less than in normal healthy persons on account of smaller range of chest expansion. Pneumonia is more common and more fatal among the smokers. Chronic bronchitis with emphysema was often present and history of asthmatic attacks was common. Opium smokers are very susceptible to infection of the respiratory tract and influenza, cold and coughs are very common among them. A number of them suffered from chronic infections of nasal sinuses.

Central nervous system.—Forty or 13.3 per cent (table VII) were found to suffer from disorders of the central nervous system. The symptoms varied from

TOTAL ..	81	25.933

a minor degree of neurosis to marked hysteria and hypochondriasis. Three individuals in this series were actually demented. We observed that the smokers were mentally sluggish though this state could be overcome

for the time being with a few whiffs of opium smoke. The heavy smokers looked dull and apathetic and seemed to have lost interest in their accustomed pursuits and cared for nobody except themselves. Their idea of time and space was not precise and they lacked the sense of responsibility. When not under the influence of the drug they are often restless and miserable. Insomnia is a very common complaint among them. Intellectual and moral deterioration are common among them.

Cardio-vascular system.—The signs of general atony were observed in most of the opium smokers. The cardiac impulse was often weak and peripheral circulation was sluggish as shown by weak and thready pulse. The incidence of heart and blood-vessel diseases was remarkably low among the series in spite of the fact that many suffered from rheumatic troubles, septic tonsils and pyorrhœa alveolaris. Even in addicts of advanced age the blood vessels were remarkably good and blood pressure was low. The arcus senilis was frequently present; varicose veins were uncommon, but hæmorrhoids were frequently seen. Besides a certain amount of anæmia which was frequently met with, no other disorders of the blood were encountered. The peculiar pale and sallow complexion and haggard look are characteristics of heavy smokers.

Gastro-intestinal system.—One hundred and eighty-seven persons or 62.3 per cent out of 300 (table VII) complained of ailments pertaining to the alimentary tract. One hundred and ten stated that they had suffered from time to time from pain in the abdomen with passage of blood and mucus in the stools. Most of these were probably cases of chronic amebiasis or bacillary dysentery who took to the use of the drug for alleviation of their symptoms. Nineteen persons in this series suffered from flatulent dyspepsia, 28 from constipation and 10 from diarrhœa. These figures are higher as compared with those normally obtained in that locality in case of non-habitues.

Eyes.—Thirty-five addicts had extensive leucomata, the result of the corneal ulceration. Most of them suffered from trachoma and blepharitis and many said that they had taken to smoking opium for trouble in connection with their eyes.

Venereal diseases.—Twenty addicts (or 6.6 per cent, table VII) gave history of exposure and contracting venereal diseases. No cases of primary syphilis were seen but secondary manifestation in the throat and skin eruptions were frequently encountered among the addicts. The use of common smoking pipes may have helped to spread the infection. No cases of neuro-syphilis were observed.

Skin.—Skin diseases were common on account of dirt and vermin with which these people were infested. Scabies was common and psoriasis was also seen in a few instances. Acne vulgaris was commonly seen associated with staphylococcal infection on the face, chest and back. The skin of the face in such cases had a thickened appearance. Ulcers of a tuberculous and specific nature were seen in some cases. Four cases of nodular type of leprosy were seen.

Premature senility.—A perusal of table VII will show that 80 (26.6 per cent) persons looked older than their actual ages. This is a common sequence of the opium smoking habit. Arcus senilis is generally seen after 40 as compared with persons beyond 60 in normal course of events.

Effects upon sexual impulses

The addicts' ideas and experience have been summarized in tabular form in table VIII. It will be observed that there were 20, or 6.6 per cent, who ascribed stimulating powers to the drug while 158, or 52.6 per cent, said that the drug was a stimulant at first but depressant later; 42, or 14.0 per cent, said that it always produced depression, while 80, or 26.6 per cent, gave out that the drug had no effect at all on sexual powers. Among certain classes of the

lower strata of society in certain parts of India, it is not uncommon to indulge in opium before the sexual act and this has been responsible for starting the opium habit in a number of cases. It is believed by the laity that, unlike alcohol and cocaine, opium by whatever method it is taken prolongs the sexual act without increasing the desire for it. Opium smoking for this reason is often resorted to along with *ganja*, *charas* and alcohol by dissipated and licentious persons. In the case of individuals who smoked large doses sexual stimulation was entirely absent. In extreme cases the habit had even led to complete loss of sexual desires and emotions.

Some of the male smokers who were smoking large doses over prolonged periods complained of complete loss of sexual desire. But when the drug was withdrawn, in a certain number of them, there was exaggeration of the desire and some suffered from frequent seminal discharges. The female smokers suffered from dysmenorrhœa and sterility. Further, the percentage of sterile marriages was much higher in our series as compared with the normal ones.

TABLE VIII

Showing the effect of opium smoking on sexual impulse

Effects	Number of cases	Percentage
1. Aphrodisiac ..	20	6.6
2. Stimulating during early stages but depressing later on.	158	52.6
3. Depressant from the beginning.	42	14.0
4. No effects noticed ..	80	26.6

DOSAGE

The addicts in this series smoked opium varying from 2 to 180 grains a day. A perusal of table IX will show that 40 persons, or 13.3 per cent, in this series smoked 1 to 5 grains a day, 82, or 27.3 per cent, 6 to 10 grains, 109, or 36.3 per cent, 11 to 20 grains, and 69, or 26.3 per cent, over 20 grains a day.

TABLE IX

Showing an analysis of 300 opium smokers according to the dosage of opium smoked daily

Daily dose	Number of cases	Percentage
1 to 5 grains ..	40	13.3
6 to 10 grains ..	82	27.3
11 to 20 grains ..	109	36.3
21 grains and up ..	69	26.3

It will be seen that the majority, *i.e.*, 78 or 62.6 per cent, smoked the drug in doses more than 10 grains a day. The average daily dose

in this series taken as a whole works out at 25 grains a day as compared with 10 grains in our series of 1,078 opium eaters (Chopra and Chopra, 1935). The addicts generally start with small doses, say between 2 to 4 grains a day to begin with, and during this period the drug is smoked occasionally as a substitute for opium eating or after a day's hard work, or on a cold winter day. The habit to begin with has not a strong hold on the individual and can be given up when the so-called necessity has passed off. It is, however, often restarted on the slightest pretext. Most of the occasional smokers after such use of opium feel after some time that they are unable to get the same effects by taking the drug by mouth as by smoking, and find some difficulty in following their ordinary routine work without indulging in a smoke once

violence. In this respect, an opium smoker differs from the *ganja* and *charas* smokers, who often are excited and maniac, and commit serious crimes, such as the act of murder. The opium smoker only commits minor offences if he cannot otherwise obtain the means of buying opium to satisfy his craving.

Duration of the habit

In 70 per cent of the habitués the habit had lasted for over 10 years (table X), in 20.3 per cent from 5 to 10 years, and in the remaining 9.6 per cent less than 5 years. In opium smokers of under 5 years' duration, the ætiological factor was generally disease or ailment, the euphoric factor being less prominent. In the addicts in which habit had lasted up to 10 years, the disease factor may or may not play a part; in

A group of opium smokers.

in 24 hours. The habit thus becomes firmly established.

It was also observed that those starting the drug under 20 years of age or between 21 and 30 years increased the dose rapidly and reached the maximum limits within three to four years. These are young individuals in whom association, euphoria and sexual factors are the main reasons for smoking the drug. When the habit is formed on account of physical debility, pain, rheumatism, etc., the addict as a rule remains satisfied with a smaller dose, e.g., less than 5 grains a day.

Opium smoking and crime

It was not possible to trace any relation between opium smoking and crimes of violent nature. The crimes committed by opium smokers as a rule were of minor character because the addict being lazy and indifferent dislikes violent physical exertion and therefore is incapable of committing daring acts of

those of more than 10 years' standing, pleasure and association were the main causes.

Diagnosis of opium smoking habit

An opium smoker will endeavour to conceal his habit as long as possible. He realizes that his profession or business will suffer if this is discovered. In the majority of

instances he knows that he is doing wrong. The critical time comes when he cannot get the drug when he needs it and the abstinence symptoms set in. The appearance of nervousness and a feeling of uneasiness indicate that it is time he should have the drug. If he still does not get it, his sufferings increase and he gets muscular pains, cramps, and sometimes diarrhoea. These are the usual symptoms of sudden withdrawal of the drug and their intensity varies in different individuals, according to the doses they take and the time the habit has lasted. Ordinarily an addict never allows himself to come to this condition, as he gets his dose as soon as he feels the call for it and this restores his equilibrium. If, however, his supply is not forthcoming or is delayed, the abstinence symptoms set in and in this condition the diagnosis of the habit can be readily made.

The other period during which the condition can be diagnosed is shortly after indulgence in the drug when the addict is under its influence. If the dose is not adjusted and a larger dose than usual is taken, the addict becomes drowsy and may even be found asleep at some unusual place and at some unusual hour, when his condition becomes apparent to his friends or employer. These are the two things in the life of every addict which sooner or later come to pass. With those taking larger doses the chances of discovery are greater, as the abstinence symptoms in them are severe and they are likely to overdose themselves. Finally, attempts have been made to diagnose opium smoking by detection of morphine in the urine, but even micro-methods are uncertain, especially with those who smoke small doses. Quite recently, however, Tosomei and Li-cho-zen (1936) have described in a League of Nations' publication a test for quantitative estimation of morphine in the urine, by the aid of which they claim to be able to detect clandestine opium smokers and morphine addicts, also to deduce the amount of morphine consumed or injected. The present authors however follow the method of Deckert (1936)* with success in case of opium eaters.

* Ten c.cm. of the urine are heated with 0.3 gm. of Na_2CO_3 until the first bubbles rise and is then quickly cooled. It is then transferred to a separating funnel and thoroughly shaken with 10 c.cm. of acetic ether. After the layers have separated, the acetic-ether layer is transferred to a small porcelain dish through a filter-paper and evaporated to dryness on a water-bath. The residue is diluted in 0.25 c.cm. of water with one drop of nitric acid (sp. gr. 1.15) and a drop of 10 per cent ammonium molybdate solution added. After careful whirling of the porcelain dish, the contents are filtered through a compressed-cotton plug placed in the upper part of the neck of a funnel. The dish is rinsed with two successive quantities of water (0.25 c.cm. and 0.15 c.cm.) which are passed through the filter. The cotton plug is then passed down to the lower opening of the funnel, so that no filtrate remains in the funnel. A drop of 2 per cent solution of ammonium vanadate is then added and well mixed. Depending on the morphic content a turbidity develops.

OPIUM SMOKING AND OPIUM EATING

Smoking and eating of opium are different aspects of the same problem though the former is believed to be more harmful than the latter. The use of opium *dross* is very uncommon in this country and it is admitted that this practice is much more harmful than smoking of opium.

The Excise Commissioner of Burma some years ago undertook an enquiry into the question of the relative harmfulness of opium smoking and opium eating. He came to the conclusion that in regard to the individual addict there is no difference in the degree of harmfulness. When larger masses of humanity are considered, however, smoking appears to be more harmful than eating, because it is more likely to attract new devotees than taking of opium by mouth. These views were accepted, and the Government of Burma in 1924 enforced compulsory registration of opium smokers and allowed no new smokers to be registered. Six months after this compulsory registration was brought into force.

No scientific data are available to support the view that smoking of opium is more harmful than eating to the individual addict. The opium smoker needs very much larger quantities of opium to satisfy his craving than the eater, but, in spite of the smaller quantities of the morphine absorbed, the practice appears to be more harmful. The harm done cannot depend on the amount of morphine absorbed during smoking and eating. That the opium smoker does not absorb all the morphine contained in the opium is proved by the fact that the *dross* remaining in the pipe contains large quantities of morphine. The percentage of morphine in the *dross* depends upon the percentage of morphine in the prepared opium smoked, and the type of pipe used and on the way it is smoked. Experiments in the Straits Settlements indicate that the smoke from an opium pipe does not ordinarily contain more than 1/10 of the total amount of morphine contained in the opium smoked. When a man eats opium he absorbs almost all the morphine contained in the dose. It would thus appear that other factors are involved which can only be ascertained by further study.

Opium smoking is generally looked upon with more disfavour than opium eating, partly because it is considered to be more injurious and partly because it is far more expensive both as regards time and money. The process of preparation is a long one and the actual smoking naturally takes longer than swallowing pills or a mixture of opium and water. As regards the difference in the expense between the two forms of consumption, this may be judged from the fact that those who require 180 grains daily as smokers may be content with eating only 10 grains a day. For these reasons the smoking of opium is very often abandoned during later

stages of addiction when the dose has become very large. The abstinence symptoms in the smokers are more pronounced and they often undergo terrible mental agony and sufferings, often worse than opium eaters. The smoking habit more often is the outcome of the euphoric or pleasure-giving effects of the drug, while such causes of the disease as fatigue and old age frequently produce the habit of eating opium. Further, smoking of opium attracts the younger people while opium eating is generally the habit of older age. The increase in dosage in case of smokers is much more rapid and marked probably due to the fact that the amount of morphine absorbed is smaller.

The chemical changes which the constituents of opium must undergo by drastic heating during the process of preparation for smoking must be considered. Their exact nature is not known but it would appear that with each heating the effect of opium becomes more potent and of greater danger to the smoker.

The active principle of opium smoke.—Dr. Pott of the Pharmacological Institute of Freiburg has actually demonstrated that morphine can be sublimed unchanged and therefore is actually present in the opium smoke. Furthermore, he has succeeded in demonstrating that the action of the smoke is due to the presence of undecomposed morphine. Indeed some of the more subtle and characteristic toxicologic effects of morphine can be produced by inhalation of opium smoke or its condensation products. It is interesting to note that Pott succeeded in inducing specific morphine reactions in mice by injecting preparations made from the blood of larger animals that had been made to inhale opium smoke.

In evaluating the effects produced by smoking, the non-alkaloidal constituents must also be taken into consideration. It is quite probable that the alkaloidal constituents are not solely responsible for the effects produced on the smokers. It is probable that the products of combustion might also play an important part. In the case of tobacco, a considerable amount of work has been done and the conclusions regarding the constituents of the smoke which are harmful are definite. Similar studies in the case of opium smoke were taken up by Dixon, but unfortunately the work was not completed and further investigation is necessary to come to definite conclusions.

Tobacco and opium smoke.—In table XI are given the composition of the smoke obtained from cigarettes and opium pipes, in conditions approximating to those which occur in smoking.

It will be seen that in the opium smoke, nicotine and carbon monoxide are entirely absent and these form the chief active constituents of tobacco smoke and are responsible for many of the ill effects that are produced. Such symptoms as vertigo, tremors, nausea and amnesia for the recent events are absent in

TABLE XI

Showing composition of opium and tobacco smoke according to Dixon

	100 gm. tobacco burnt as cigarettes	100 gm. <i>dross</i> opium containing 7.35 per cent morphine
Hydrocyanic acid	0.080	0.010
Pyridine ..	0.146	0.147
Nicotine ..	0.165
Ammonia ..	0.360	0.395
Carbon monoxide	410 c.cm.
Morphine	0.016 (0.1 from <i>chandru</i> smoke)

case of opium smokers while they are common among tobacco smokers. In the case of opium smoke on the other hand, morphine and pyridine bases are predominant and may perhaps by producing synergistic effects be responsible for producing the effects on the central nervous system.

Prevention of the habit

Education and improved standard of living are the most effective forces that have operated against the spread of the habit in this country. With the improved standard of living follows an increase of purchasing capacity of the population in general which creates a demand for and possibility of affording healthful recreations, such as outdoor games and amusements in the form of cinemas, etc. For these reasons the habit has greatly declined in certain industrial areas, such as in Digboi and various tea gardens in Assam, whereas in the undeveloped parts it is prevalent to a considerable extent. Unless the general, hygienic and economic conditions of the people are improved prohibitory legislation will not be effective.

Treatment of the established habit

The treatment of the opium smoking habit is the same as that of opium eating and has been described by the present authors in detail in a previous paper (1937). Experience in India has shown that the opium smoking habit is more difficult to get rid of than the opium eating habit. When treating these cases, the personality of the addict, the age, the physical condition, the intercurrent diseases and ailments from which he has been suffering, the doses he is taking, and the duration of addiction are all important factors and should be kept in view. We found that the young and healthy addicts taking moderate doses responded to the treatment much more readily than those who are advanced in age and had been taking large doses, for over prolonged periods. An effective cure requires firm will-power on the part of the addict and a determined resolution not to succumb to the temptation again. In order to effect a permanent cure and to prevent the addicts from relapsing into

the habit, it is necessary to keep them away from other smokers. This is difficult in the case of addicts who undergo ambulatory treatment outside. The patients we treated in the Carmichael Hospital for Tropical Diseases were not allowed contact with outsiders and were kept under strict supervision. The cure of confirmed opium smokers should be undertaken in hospitals or an institution where the necessary strict control can be exercised. Our experience is that, if the segregation is not complete and prolonged, there is a likelihood of a relapse occurring when the individuals get into the company of smokers again. It is therefore advisable to adopt measures of a social character aiming at keeping the cured persons in favourable surroundings and to provide them with moral support to withstand the temptation.

SUMMARY AND DISCUSSION

In part I, the history of opium smoking in India and its incidence in various parts of the country have been described. Even up to the beginning of the nineteenth century no writer has recorded smoking of opium by the people of India, although it prevailed in China. Tobacco smoking was introduced into India in the latter part of the sixteenth century and it is evident that in the case of India, as of China, opium smoking was simply an outcome of tobacco smoking. It is uncertain how this habit was brought into this country, but fortunately it never assumed such a menacing aspect as it did in China. Our present enquiries show that the habit of smoking opium in one form or other is met with on a small scale in many of the large towns in India. A general survey of the incidence of the habit has been carried out in different provinces and the results have been summarized. It would appear that the habit of smoking has considerably declined during the last 30 years. Opium smoking has always been looked down upon throughout the country and stringent regulations have been enacted against it. In most parts of India, therefore, this is a very uncommon method of consumption of opium at the present time. The only exceptions to this rule are Assam and the Central Provinces where opium smoking is almost as common as opium eating.

In part II the methods of preparing opium for smoking, the modes of indulgence, the type of persons addicted, and the control exercised by the state have been discussed.

In part III an analytical study of 300 cases of opium smoking studied by the authors is given. The following conclusions can be drawn :—

(i) *Causation*.—From the field studies made in the areas where the practice is more common, social and economic factors were found to be instrumental in the spread of this habit. The main causes of addiction in these series were:—
(1) Association with other addicts which

accounted for 50 per cent of cases; (2) diseases or minor ailments for which no medical advice was sought, 33.3 per cent; (3) hard work, worry or strain, 13.3 per cent; (4) substitute for alcohol, 3.4 per cent.

(ii) *Duration*.—In 70 per cent of the addicts, the habit had lasted for over 10 years, in 20.3 per cent from 5 to 10 years and in the remaining 9.7 per cent less than 5 years. In opium smokers of under 5 years' duration, the aetiological factor was generally diseases or ailments, the euphoric factor being not prominent. In the groups in which habit had lasted up to 10 years, disease may or may not play a part in causation; in those of more than 10 years' standing, pleasure and association were mainly responsible for the habit.

(iii) *Age of commencement*.—The commonest age at which the habit is contracted is between 21 and 30 years and as many as 40 per cent in this series started it at that period of life.

(iv) *Dosage*.—The dosage in our series ranged from 1 to 180 grains of opium daily and in some cases much larger amounts were smoked. The majority, i.e., 66.1 per cent, smoke doses larger than 11 grains a day. Doses of those who smoked opium to enable them to do hard work varied from 6 to 10 grains and of those who smoked it for euphoric purposes and as a substitute for alcohol, 21 grains and over. It appears that when the habit is acquired by association, the daily amount consumed is increased rapidly, the majority in this group taking over 10 grains a day. When the habit is formed on account of physical debility, pain, rheumatism, the addicts as a rule remain satisfied with much smaller doses (often less than 5 grains daily).

The effect on the health of moderate smokers has also been discussed. The excessive smokers are as a rule thin, emaciated and underweight individuals. They have a shallow and muddy complexion, with dull, lustreless and sunken eyes. The habit, when indulged in to excess, imparts a pallid and haggard look to the features. Persons smoking very large doses showed rapid loss of weight and in a few instances suffered from general cachexia. The skin loses its natural appearance and is often pale and dry with scales. The nails, teeth, and hair are also often diseased. When the drug has been abused for a long time the sexual impulse is deficient and often wanting altogether. Throat is often irritable and the addict is constantly subject to attacks of tonsillitis, pharyngitis and chronic bronchitis and emphysema.

The daily consumption of large doses of the drug causes stagnation in the alimentary tract as a result of which the appetite diminishes and the food taken is not properly assimilated. There may be constipation alternating with diarrhoea. The addict is more liable to be affected by vicissitudes of weather and insanitary surroundings on account of his lowered vitality.

The stimulant effects of the drug are appreciated by the habitué only during early stages

of addiction. Gradually these disappear and in a few months necessity for further increase of the dose is imperative if the desired euphoric effects are to be obtained. This produces a weakening of the mental faculties of the addict and there is subordination of everything towards the one object of satisfying the craving. Opium smoking appears to become the main object of life. The mental effects produced are proportionate to the dosage consumed and general power of resistance of the habitué. Prolonged and excessive smoking produces a lethargic state of mind, with dulling of the mental process, gradual loss of will-power, and neglect of work. The facial expression in the case of the excessive consumer is vacant and a number amongst them suffer from tremors of the fingers and hands. The intellectual faculties show a rapid decline and most of the habitués become indifferent to their surroundings. Some of them become so dull and apathetic that even hunger and extreme poverty give them no incentive for work. In cases of excessive smokers the moral faculties are also affected. They become unreliable and dishonest and will do anything, however nefarious, to secure opium to satisfy their craving. The sense of discrimination between right and wrong is considerably weakened.

The degree of the harm resulting from opium smoking depends upon a number of factors, e.g., race, environment, economic conditions, dosage, age and occupation of the addicts. Amongst the series of addicts studied by us it was observed that Chinese addicts as a rule suffered less than the Indian from the effects of the large doses. This is due to the fact that they can exercise better control over themselves, and very often keep to moderate doses which the age-long experience with the use of the drugs has taught them. They measure their dose accurately and with precision and keep the daily consumption within proper limits to a quantity that does not interfere with their earning capacity by undermining their general health. Although the average daily dose taken by the Chinese addicts was nearly two to three times larger than by Indian addicts, the ill effects were less marked in the former. This may possibly be the reason why opium smoking has established itself with stronger footing in certain parts of Assam and Burma, which are inhabited by people racially allied to Chinese.

The effects of an unhygienic mode of living, neglect of general health, lowered standard of living, and the use of a common pipe are responsible for the spread of such diseases as syphilis, tuberculosis, and pyorrhœa.

In many of the smokers, the cost of the drug consumed is more than their earnings. In others 30 to 60 per cent of their earnings are spent towards the purchase of the drug. With the small amount of money left after buying opium it is difficult for the addict to maintain himself and

THE INCIDENCE OF RHEUMATIC INFECTION IN INDIA

(AS JUDGED BY THE ADMISSION AND POST-MORTEM RATES AND BY THE CLINICAL EXPERIENCE OF TEACHING PHYSICIANS AT THE MEDICAL COLLEGES AND SCHOOLS OF INDIA): PART I

By V. S. MANGALIK, M.D. (Luck.), D.C.P. (Lond.)
Lecturer in Pathology, Medical School, Agra
and

H. STOTT, M.D., F.R.C.P., D.P.H.
LIEUTENANT-COLONEL, I.M.S.

Professor of Pathology, and Physician, King George's Medical College Hospital, Lucknow

ADMISSIONS FOR ACUTE AND FOR SUB-ACUTE RHEUMATIC INFECTION

1. Type incidence

Of the nine admissions for acute rheumatic infection (1930-36) in the Thomason Hospital, the admission rate for 1,000 medical admissions works out at 1.17. Of these admissions, four or 44 per cent were for acute rheumatic fever, an equal number for endo- or peri-carditis and one or 11 per cent for chorea. No mention is made in the records of the presence or absence of

(Continued from previous column)

his family. In order to make both ends meet the addict tries to stimulate his physical energies artificially by further increasing the dose and tries to do more work which further undermines the health, thereby further decreasing his working and earning capacity, and after some time there is total loss and the addict becomes useless to himself and society. In the case of well-to-do and healthy individuals who can afford nutritious food, the adverse effects may not be easily discernible during the early stages. The poor classes suffer from the very beginning as they are ill-nourished and have a lower power of resistance. The incapacity caused in the latter is more serious and responsible for considerable economic loss to the country. These factors are probably responsible for backwardness and slow progress of various parts of Assam and the Central Provinces.

Excessive indulgence in opium smoking produces:—(1) Economic loss by reducing the earning capacity of the addicts; (2) damage to health and loss of physical energy and deterioration of intellect; (3) curtailment of longevity.

rheumatic nodules in these cases of poly-synovitis or carditis groups. Table I shows the admission rate per 1,000 medical admissions :—

There were no admissions during the hot dry months, and the maximum admissions were during the damp months of September and

TABLE I

Years	Poly-synovitis	Endo-carditis	Peri-carditis	Chorea only	Total acute rheumatic infection	Total medical admissions	Acute rheumatic infection per 1,000 admissions
1930 to 1936 ..	4	2	2	1	9	7,649	1.17
Average per year	0.57	0.28	0.28	0.14	1.28	1,092	1.17

2. Annual variations

The total annual medical admissions have gone up a little year by year—from 810 in 1930 to 1,278 in 1936—and the admission rate per 1,000 for acute rheumatic infection seems to be variable—no case in 1930–34, and 1935 had the maximum incidence of these infections.

The actual figures for the successive seven years are shown below in table II :—

TABLE II

Year	Medical admissions	Acute rheumatic infection per 1,000 admissions
1930	810	0
1931	1,171	0
1932	977	0
1933	1,069	0
1934	1,152	0.8
1935	1,192	6
1936	1,278	0

3. Monthly incidence

The distribution of these acute admissions for seven years, according to the month of admission, is shown in table III :—

TABLE III

	Acute rheumatic infection admissions	Climate	
April ..	0	Hot dry months	Nil
May ..	0		
June ..	0		
July ..	0	Hot damp months	7
August ..	0		
September ..	6		
October ..	1		
November	1	Cold dry months (Xmas rains)	2
December	1		
January ..	0		
February	0		
March ..	0		
TOTAL ..	9		9

October. Agra is a comparatively dry place, with an average annual rainfall of about 20 to 25 inches only, and it is significant that six out of nine cases have been admitted during the hot damp months of September, when the rainfall is heavy and the liability to chill high.

4. Age incidence

The age distribution for acute rheumatic infection is set out in table IV :—

TABLE IV

Years	Fever and poly-synovitis	Carditis	Chorea	Total	Per cent
0 to 5	0	0	0	0	0
5 to 10	1	2	0	3	33.3
10 to 15	2	2	1	5	35.3
15 to 20	0	0	0	0	..
20 to 25	0	0	0	0	..
25 to 30	1	0	0	1	11.3
30 to 35	0	0	0	0	..
35 to 40	0	0	0	0	..
40 to 45	0	0	0	0	..
45 to 50	0	0	0	0	..
50 to 55	0	0	0	0	..
TOTAL	4	4	1	9	100

Figures, though small, indicate how 88 per cent of cases were admitted below 15 years of age and the age of these varied from 5 years to 15 years. One hundred per cent were below 30 years and not a single case over 30 years.

5. Sex distribution

All the nine cases of acute rheumatic infection were males. No case in females was admitted.

ADMISSIONS FOR CHRONIC RHEUMATIC MITRAL DISEASE

1. Type incidence

Table V shows the admission rate per 1,000 medical admissions :—

TABLE V

1930 to 1936	WITHOUT HEART FAILURE				WITH HEART FAILURE			Grand total	Per milli medical admissions
	Stenosis only	Combined S and R	Regurgitation only	Total	Congestive heart failure only	Auricular fibrillation	Total		
Actuals ..	22	33	44	99	24	8	32	131	17.1
Per cent ..	22	33	44	..	75	25
Average per year	3	5	6	14	3	1	4	19	17.1

About one-third of the chronic mitral disease cases were without heart failure and about one-third with heart failure. In the former group there was valve defect of stenosis only in 22 per cent, of stenosis and regurgitation in 33 per cent, and regurgitation only in 44 per cent. In the heart-failure group, there is no record of cases with congestive heart failure and auricular fibrillation. Seventy-five per cent were of congestive heart failure and 25 per cent were of auricular fibrillation only.

There is an obvious difference, therefore, between the various figures obtained in this hospital and those in King George's. The striking difference seems to be in 44 per cent of cases being of mitral regurgitation and only 22 per cent of stenosis. I am inclined to think that stenosis alone or stenosis with regurgitation is a more frequent finding than regurgitation alone. Mitral diastolic murmur on which the stenotic lesion is diagnosed is very frequently missed and the classical crescendo, presystolic murmur, is comparatively rare—hence most cases are diagnosed only as mitral regurgitation.

2. Monthly incidence

The distribution of these heart-failure cases from primary chronic mitral valve disease according to the month of admission has been as follows :—

TABLE VI

Primary M. V. heart-failure cases		Average admissions, per month
April 4	Hot dry months	9
May 8		
June 15		
July 13	Hot damp months	9
August 9		
September 11		
October 4		
November 14	Cold dry months	10
December 4		
January 13		
February 15		
March 5		

More or less equal distribution of cases in various months.

3. Age incidence

Age incidence of the admission for primary chronic mitral valve disease, with or without heart failure, is set out in table VII :—

TABLE VII

Years	Number of cases	Per cent	
0 to 5	0	0	25
5 to 10	6	5	
10 to 15	25	20	
15 to 20	20	16	44
20 to 25	19	15	
25 to 30	17	13	
30 to 35	13	9	24
35 to 40	10	8	
40 to 45	9	7	
45 to 50	5	4	7
50 to 55	2	2	
55 to 60	1	1	
TOTAL	127	100	

Whereas 25 per cent were under 15 years, 69 were under 30, and 93 per cent were under 40 years of age. As will be seen from table IV, 88 per cent of cases of acute infection were admitted below 15 years, and it seems that the main incidence of heart failure and chronic mitral disease would fall between 20 and 30 years—the period required for these patients to seek admission from disabilities connected with circulatory failure.

4. Sex distribution

Of the 127 cases of chronic rheumatic heart disease, 16 were in females and 111 in males. It is well known how various social customs like 'purdah' in this country interfere with correct estimation of the distribution of a disease in the two sexes. Hence these figures cannot be deduced to give any idea of distribution of this condition in the two sexes.

Post-mortem rates

There were no post-mortem examinations done on acute rheumatic infections, but the results of post-mortem examinations in chronic

rheumatic mitral diseases are summarized as follows :—

1. Type distribution

TABLE VIII

Chronic rheumatic mitral disease

Uncomplicated	With auricular fibrillation	With congestive heart failure
0	1	5
Total post-mortem examinations, 1930 to 1936.	118	
Rheumatic heart disease, 1930 to 1936.	6	
Percentage incidence	5.1	

Only heart failure cases due to primary disease of mitral valve have been included. Heart failure due to other conditions like chronic bronchitis and emphysema, chronic myocardial disease or aortic disease has been excluded.

2. Valve affected

Of six mitral lesions, four were of pure stenosis and two of combined stenosis and regurgitation.

3. Previous rheumatic history

This was obtained in half of these cases.

4. Sex and caste distribution

All were Hindu males.

5. Age distribution at death is shown in table IX :—

TABLE IX

Years	0/5	6/10	11/15	16/20	21/25	26/30	31/35	36/40
Mitral heart-failure cases.	0	0	1	0	1	3	1	0

All died between 11 and 35 years. Maximum incidence of death was at 30 years.

Conclusions

The hospital records of cases and the post-mortem records have been analysed in the above pages, and it helps to throw light on some of the problems connected with rheumatic infection in Indians. The following conclusions may be drawn :—

(1) That acute rheumatic infection in India, with poly-synovitis, carditis and chorea, though rare in the hospital-going class of Indians, is a definite clinical entity to be seen in India.

(2) That the incidence of chronic rheumatic infection is far more common. For every case of acute rheumatic infection admitted in the hospital during the period under review, 14 cases of chronic valvular disease, mostly mitral

and of undoubted rheumatic origin, sought admission :—

Acute rheumatic infections in 1930-36 = 9.

Chronic rheumatic infections in 1930-36 = 131.

(3) That one is justified in drawing the conclusion that the initial rheumatic infection in Indians is rarely fulminating and acute, and rarely compels the patient to seek medical advice in hospital and is probably of a slow, insidious course and onset—mostly vague pains in the body and joints, not severe enough to confine the patient to bed or to seek hospital admission.

(4) The most common age for acute rheumatic infection is between 5 and 15 years.

(5) The most common age when the patient seeks hospital aid from cardiac disabilities connected with chronic mitral valvular lesion is between 20 and 35 years of age—about 10 to 15 years after the initial infection.

(6) There is no definite distribution in the sex or caste of the patients, nor is the monthly admission of any great significance.

(7) Rheumatic nodules are very rare.

The clinical experience of physicians attached to the Thomason and Lady Lyall Hospitals in Agra. They have recorded their independent opinion, incorporating their experiences of private practice as well. The opinion seems to bear out the facts, in most cases, as revealed by the statistics above.

Note by Lieut.-Colonel J. C. Bharucha, I.M.S., Principal, Medical School, Agra, and Physician, Thomason Hospital, Agra :—

Cases of rheumatic fever of acute type, with poly-arthritis, fever and responding to salicylates are seen amongst the well-to-do class of people in private practice. I have seen about half a dozen cases of this type, mostly in boys and girls of school-going age—and at least in two of them I could see the developing mitral lesion—but such cases have not come under my observation in hospital practice, quite likely because the majority of such patients are either not ill enough to seek hospital admission in a big city, or they are treated by other systems of indigenous medicine.

On the other hand, we do get a fairly large number of cases seeking admission into the hospital for failure of compensation, and showing mostly mitral lesions, either stenosis only or both stenosis and regurgitation, and most of them give a history of pains in the joints. As such types of cases come up in hospital practice, I have no doubt that rheumatic fever, if not of a very acute type, does occur in India. It is likely that its onset is insidious and the course not so fulminating as in the West. I have seen one case of rheumatic nodules, coming on in a case of mitral disease, when the failure of compensation set in. It is likely that these nodules were an evidence of increased activity of the underlying rheumatic process leading to

a failure of compensation. I have seen one or two cases of chorea in young girls.

Note by Dr. S. Chaudhuri, W.M.S., Lecturer in Medicine and Physician, Lady Lyall Hospital, Women's Medical School, Agra :—

After nine years of experience in the women's hospitals in Delhi and Agra, I have come to the conclusion that rheumatic infection is far from uncommon in India. It seems to take on a sub-acute and insidious onset and course and thus 'rheumatic fever' frequently remains undiagnosed until the patient is forced to seek medical advice for some form of cardiac disability precipitated by pregnancy or reactivation of disease.

I have seen six cases of acute rheumatic fever which had poly-arthritis and high temperature; three of these showed choreiform movements, none showed any rheumatic nodules and they all responded to salicylates. I have at present in the medical unit of the Lady Lyall Hospital, Agra, a case, 30 years of age, with a fulminating form of acute rheumatic fever—continuous high temperature, of acute poly-arthritis, choreiform movements localized to one arm, leucocytosis, a very high sedimentation rate (100 mm. at the end of one hour by Westergreen's technique), and responding very well to large doses of salicylates. No rheumatic nodules are seen.

On the other hand, I have seen a larger number of cases of chronic valvular disease of the heart, mostly mitral endocarditis with or without congestive heart failure; a good percentage of these cases showed auricular fibrillation. I have seen a few cases of hemiplegia of embolic origin with mitral disease and one case of mitral disease ending fatally after sub-acute bacterial endocarditis, confirmed at the post-mortem table. In most of these cases one could obtain, on careful and searching enquiry, a previous history of attacks of joint pains or vague aches and pains with fever dating from early childhood. I have absolutely no doubt in my mind that almost all of these cases were frankly rheumatic in origin.

The following table gives the actual admissions to the Lady Lyall Women's Hospital, Agra, for the past three years :—

	1934	1935	1936
Total medical admissions.	3,433	3,616	3,685
Mitral disease ..	4	6	4
Congestive heart failure.	4	10	6
Auricular fibrillation.	1	0	0

Note by Dr. G. N. Vyas, M.D., M.R.C.P. (Edin.), for over 10 years Lecturer of Medicine and Physician, Thomason Hospital, Medical School, Agra :—

It can be freely stated in general terms that rheumatism in all its forms is less common in

(Continued at foot of next column)

THE SUBCUTANEOUS NODULE OF RHEUMATISM

By P. G. GOLLERKERI, M.D.

(From the Departments of Pathology, Medical College and General Hospital, Rangoon)

THE rheumatic infective agent has been observed to attack particularly fibrous connective tissues of certain parts of the body. The myocardium gets the lion's share of the attention in the young, and the connective tissue around the joints and at muscle and tendon

(Continued from previous column)

India than in European countries, particularly in Great Britain.

The standing points of interest regarding the types prevailing in India are as follows :—

(1) Acute and flagrantly-active phases of the disease are conspicuously rare. Thus Sydenham's chorea, rheumatic nodules, acute rheumatic fever with poly-synovitis and acute rheumatic endocarditis are not so often met with in clinical and hospital practice in India as in England. But the existence of each of these forms is decidedly beyond challenge.

(2) The type of rheumatism that commonly prevails in this country is a mild and chronic form with ill-defined and vague pains in joints and tendons. It is not at all uncommon to find a negative history of rheumatism in a frankly rheumatic case of mitral stenosis.

(3) Valvular diseases of the heart of rheumatic origin are fairly common when compared with the rarity of other manifestations of rheumatism. The lesions in all probability are due to previous chronic rheumatic endocarditis. The common valvular lesions arranged in the order of their frequency are :—

(1) Mitral stenosis and regurgitation (double mitral).

(2) Mitral regurgitation.

(3) Mitral stenosis (pure stenosis is somewhat rare).

(4) Extensive mitral stenosis and regurgitation with slight aortic regurgitation.

(5) Double mitral as well as double aortic lesions.

(4) Arthritic manifestations are more conspicuous in adults than in children.

(5) Pericardial involvement occurs in a very small proportion of cases.

(6) Preponderance of males over females is conclusive owing to the deterrent effect of purdah on hospital admissions.

(7) The age incidence conforms to the European type. Most of the manifestations occur in the rheumatic period of life, i.e., 10 to 35 years.

(8) The association of infected tonsils with valvular damage is too common to be ignored as an aetiological factor of importance.

attachments in the older subject. Serous membranes like the pericardium and synovial membranes are also liable to be attacked. No matter where the focus is localized, the history of an active lesion is described as fairly characteristic, just as is the structure of a tuberculous focus. The chief feature of the rheumatic process histologically is a proliferative phenomenon with a small degree of degeneration or necrosis which may or may not be recognizable. An exudative factor may accompany this proliferative lesion, specially in connection with the affection of the serous membranes or when the lesion is superficially situated.

In muscular rheumatism, the lesion may tend to be localized near the attachment of the muscle to the bone rather than the belly. Thus, ends of bones, long or otherwise, are especially vulnerable points for the activity of the rheumatic virus. Again, as the muscle gets attached to its bone, it comes to lie, when it approaches the bone, more superficially in relation to the skin above. This adds to the possibility of the lesion becoming infected with staphylococci from the skin surface. The staphylococcal infection is a feature of great importance as it may confuse the true underlying cause and nature of the lesion, when the histological structure comes to be studied.

Acute rheumatism, particularly in the child and young adult, is said to be accompanied by erythematous nodules over bony prominences near the large joints of the extremities. These, though not specific to rheumatism and occasionally met with in tuberculosis, are superficially situated, cutaneous rather than subcutaneous.

In the course of the last three years, four subcutaneous subacute lesions attracted attention because of a similarity of their histological structure to the classical picture of the Aschoff bodies. None of these four cases, however, gave a definite history of joint pains of a rheumatic nature nor clinically showed a rheumatic heart lesion. But the anatomical situation of these four lesions and the duration of three of them pointed to their rheumatic nature.

Before proceeding to report these four cases, a brief histological description of a true rheumatic lesion would not be out of place.

The Aschoff body is the result of proliferation of certain kinds of inflammatory cells with a varying degree of exudative element added. At first, there is a degenerative change in the collagen of the part affected (fibrinoid degeneration of Klinge) which may or may not be visible after the subsequent proliferative phenomenon. The proliferation is para-vascular in distribution, being situated in relation to the adventitia of the small arteries, but it is at one side of the vessel and does not surround it. The architecture of an Aschoff body has in it the following four components:—

- (1) Centre of necrotic (or degenerated-Klinge's fibrinoid degeneration) material which may not be visible.

- (2) Aschoff cells. Large epithelioid type of cells showing one or more nuclei and basophile-staining cytoplasm. These giant cells are probably the result of the exudative element of the process, with swelling and oedema of the cells.
- (3) Lymphocytes and plasma cells and occasionally polymorphonuclears. The last may be so numerous as to swamp the characteristic architecture of the whole structure. This is particularly true when the serous membranes are attacked and in the superficial lesions about to be described.
- (4) Fibroblastic proliferation with subsequent fibrosis.

Subcutaneous nodules have been described in the acute rheumatic conditions of children and adolescents, as well as in the chronic rheumatoid conditions of adults. Klinge believes in the identity of the histological picture of these two conditions, though recently Collins (1937) disputes it after a very careful study of nine cases. Of the four cases about to be cited, if only age is taken into account, case 4 (52 years) may fall into the rheumatoid group with possibly case 1 (39 years). The ages of the other two would put them definitely in the rheumatic class. Thus, with a similar histological picture of the lesions, it corroborates Klinge's observation. In none of the four cases was there a definite history of trauma preceding the development of the lesion.

Case 1.—Burman male, 39 years, admitted into hospital for an inflamed tender swelling on the side of the left shoulder blade. It became acutely painful about two and a half weeks prior to admission. The swelling is of two years' duration and varied in size during this period. There was no past history of fever and joint pains. Wassermann reaction—negative. Physical examination of the various systems—normal.

Operation report.—A deep subcutaneous localized abscess definitely circumscribed and surrounded by a very fibrous capsule. Culture from the pus showed *Staphylococcus aureus*. Clinical diagnosis: tuberculous process with secondary infection. Tissue sent for a histological examination.

Histological report.—Sections suggestive of an acute exacerbation of a subacute inflammatory process of the subcutaneous region. Superficially, the cells are mostly of the neutrophilic polymorphic variety with here and there a mononuclear tissue cell or a giant cell. Deeper down towards the fibrous capsule the cell infiltration is mainly that of mononuclear round cells, plasma cells and giant cells, the last being both of the mono- and multi-nucleated varieties. There is a good deal of capillary proliferation and the cell infiltration is particularly grouped about the lumina of these. Then follows the thick fibrous wall with an irregularly disposed adipose tissue (subcutaneous) in and around it. The structure is therefore suggestive of a subcutaneous rheumatic process with acute exacerbation by a staphylococcal infection.

Case 2.—Burmese female, 18 years, admitted into hospital for treatment of a swelling at the lower end of the right thigh and the knee joint of one year's duration. It is hot to the feel and seems to be attached to the joint. It is soft and free from the skin. The pain is worse at night and there is heaviness on that side when walking. Teeth and gums—bad. No anaemia. X-ray examination—no bony lesion. Urine—negative findings.

Operation.—Tumour opened up and rusty fluid let out. Part of tumour sent for histological examination.

Histological report.—Sections show a vascular and loose connective tissue with a subacute inflammatory cell infiltration. The cells are particularly numerous around the vessel lumina. Mostly there are mononuclear round cells of the lymphocyte variety with a good sprinkling of plasma cells. There are no multinucleated giant cells, though here and there are seen a few larger epithelioid cells. The rest (greater part) is made up of thick fibrous tissue.

Case 3.—Hindu male, 25 years. Soft suppurating tumours occupying the greater part of the upper half of the back on either side of the spine. Duration two years. ? caries spine.

X-ray examination—no bony lesion demonstrable.

Histological report.—Suppuration in a subacute inflammatory process in thick fibrous connective tissue. The cell infiltration is more marked towards the cavity of the abscess. The polymorphonuclears preponderate, but towards the wall the cell types vary and are more numerous and closely packed. Vascularity increases as one approaches the fixed tissue and the cells seem to group round the lumen of the vessels. Discrete masses of calcified matter are also seen in this region. The cells are of the small round lymphoid variety, plasma cells and uni- and multi-nucleated giant cells of the Aschoff type.

The structure is not suggestive of a tuberculous process, nor could it be regarded as syphilitic.

Case 4.—Chinese male, 52 years, was admitted for the treatment of a painful swelling of the right arm of two months' duration. It started with fever followed by an indurated swelling on the lateral aspect of the middle of the right arm. He was given an intramuscular injection in the gluteal region outside the hospital and, not finding any relief from it, sought admission into hospital.

Operation.—Same day as admission. A cyst-like tumour containing blood-stained fluid was noted. A part of the cyst (?) wall was sent for section.

Section report.—The tissue received was in many small pieces, all of these were sectioned in one block. Histologically, they all show a fairly vascular granulation tissue of a loose texture, with a pleomorphic cell infiltration suggestive of a subacute inflammatory process. Mononuclear round cells, plasma cells and fibroblasts are seen irregularly mixed together between the capillaries. Among these, large uni-nucleated cells with a pink-staining cytoplasm are seen in some numbers. The nucleus of these large cells is not prominent and in some not seen at all. Multi-nucleated giant cells are not seen. The number of polymorphonuclears is very small. There is no proliferation of the epithelioid type of cell nor is there any noticeable thickening of the vessels. The looseness of the tissue in which this cell infiltration and granulation tissue is developing suggests it to be a kind of degeneration of the collagen (fibrinoid degeneration of Klinge). It is not suggestive of a tuberculous process nor could it be a syphilitic condition. The histological picture and location of the lesion in the neighbourhood of an important joint, where powerful muscles get their attachment, suggest a rheumatic origin for the condition.

Discussion.—Clinically rheumatic processes are recognized by their specific activity in the heart in the young and the joints and muscles in the adult. General systemic reaction in the form of fever, pain and swelling of joints tends to be more marked in children and young adults than in elderly people. The histological changes associated with true rheumatic lesions—the Aschoff nodules—can be found, not only in the myocardium but also in other tissues, such as the blood vessels, the connective-tissue sheath of the tendons and aponeurosis and the

synovial membrane of subjects dying of rheumatic fever. The Aschoff nodule, although considered as specific histological evidence of rheumatic fever, may nevertheless turn out to be a peculiar non-specific reaction to the streptococcus occurring in the tissues of certain people, as similar bodies have been found in the heart muscle in cases of scarlet fever. The changes in the muscle and peri-articular tissues are, according to Swift, Klinge and Coombes, localized manifestations of a general reaction of the body to various infecting organisms rather than to one particular organism.

None of the four cases described above gave any history of articular rheumatism nor were there any stigmata of a rheumatic diathesis. Except in case 1, the teeth of all of them were described as 'bad'. In many cases of true rheumatism a focus of probable absorption is generally available in the mouth. Tonsillitis and sore throats come to be looked for as a routine in the clinical examination of patients complaining of rheumatic joint and heart lesions. There is some definite relationship between the finding of the streptococcus in the tonsils and throats and the development of the joint or heart manifestations. Arthritis in older people is so often associated with pyorrhœa that the connection cannot be overlooked. Pyorrhœa is a condition from which a heterogenous mass of pathogenic and saprophytic organisms can usually be isolated. Of the former the streptococcus is the most common and is almost invariably found. Again in about 8 per cent of rheumatic fevers the streptococcus has been cultured from the blood. Whether the streptococcus has been recovered from the tonsil, the throat or from bad teeth, it seems to have a definite relation to the development of lesions in the connective tissues around joints, muscles, etc. Usually the lesions are near enough to a joint to produce subjective symptoms referable to the joint itself. But if the lesion is some distance from the joint so as to be localized as a definite inflammatory focus, the true underlying cause may be lost sight of, as has probably occurred in these cases. Again, these nodular lesions may be the only manifestation of a rheumatic infection.

The long duration and the chronicity of these lesions may suggest to the clinician one of the two other common infections as the possible cause—tuberculosis and syphilis. The histology of a tuberculous process is so straightforward and definite that none but a tyro in histological diagnosis would miss it. On the other hand, syphilitic lesions are not so definite histologically. In the cell infiltration of an active syphilitic lesion, one goes by the presence of mononuclear round and plasma cells with their characteristic concentric distribution round the vessel. There is a varying degree of fibrosis and a few epithelioid cells. Giant cells of any kind are rare. But an invariable feature of syphilitic processes is the marked peri-arterial thickening

BACTERIOPHAGE TREATMENT OF DYSENTERY IN PRIVATE PRACTICE

By M. O'CONNOR, M.B., B.S. (Lond.), M.R.C.S., L.R.C.P.
Calcutta

It is important at the outset of this article to emphasize the point that it only contains an account of the use in the treatment of dysentery of bacteriophage, which the writer has found effective, and that it is not, in any way, a truly scientific treatise presenting full bacteriological and clinical data. The general principles of treatment are given, and in many cases the diagnosis is only made on the presence of mucus, blood and pus seen in the stool with the naked eye.

In private practice the financial circumstances of the patient may not always permit of a full bacteriological examination of the stool. Also a full bacteriological examination of a stool, with identification of the organism, takes two valuable days. Some of the cases treated may not have been botanical dysenteries and certainly some later proved clinically and under the microscope to be amœbic. In those reported on, Flexner infections were by far the most common, and certainly the easiest to cure. Shiga infections were more resistant. Culture reports after phage treatment are confusing and, in my opinion, of little value.

Incidentally an amœbic infection was often found in cases apparently cured by this phage treatment and one was given the impression that, in many cases, it required an added bacterial or chemical irritation to activate the *Entamœba*

(Continued from previous page)

with hyalinization noticed in the small vessels. This thickening which may be so great as to strangle the lumen of the vessel, together with the cell infiltration above described, has proved time and again in our hands to be syphilitic and corroborated by a subsequent Wassermann reaction of the blood.

Thus, we are left with the strong possibility of these lesions being of a rheumatic nature without the occurrence of the usual phenomena of joint and heart affections.

Summary.—Four subcutaneous nodules are described with reference to their clinical and histological appearance. They have a similarity to rheumatic subcutaneous nodules in their histological structure and localization. In none of the cases, however, was a clinical history of rheumatism, recent or remote, obtainable, nor were any physical signs of a rheumatic nature discoverable. The question of their being an independent manifestation of rheumatic infection is discussed.

REFERENCE

Collins, D. H. (1937). *Journ. Path. and Bact.*, Vol. XLV, p. 97.

histolytica. Cases of amœbic hepatitis frequently had no present nor previous history of bowel infection, except of a dysentery cured by phage treatment four or five years previously. This raises a question outside the scope of the present article.

The bacteriophage used has generally been that prepared by the Pasteur Institute in Shillong, but since this is not generally available to chemists in Calcutta, occasionally the French product, sponsored by d'Herelle, was used. The latter is more expensive, but equally effective.

I would like first to outline a more or less standardized treatment of dysentery with bacteriophage, and later to proceed with the discussion of the various features, my reasons for their inclusion, and which, in my view, account for the success of the treatment.

Diagnosis.—As already stated, a diagnosis of dysentery is made essentially on the discovery of mucus, blood and pus in the stool, together with a history of frequent stools. Pain, fever and acute onset may or may not be present. There may be a history of an acute attack of gastro-enteritis, *viz*, diarrhoea and vomiting several days previously, which has been relieved by sedatives. Examination of the patient may show a rise of temperature, or in the less acute cases a subnormal one. There is usually some abdominal tenderness, general in acute cases, and in the writer's experience more commonly left-sided in bacillary cases and cæcal in amœbic ones. In children it is well to keep in mind the possibility of intussusception.

If possible send, or arrange to be sent, a fresh specimen of the stool to a pathologist. If the patient has walked into my consulting room and is not acutely ill, I usually send him to the laboratory to pass a fresh stool, so that my colleagues may have every chance of finding amœbæ if they are present.

Treatment.—The patient is sent to bed, and presented with two sheets of paper, one the prescription for the chemist and the other full instructions concerning his diet and treatment.

The first reads as follows:—

R

(i) Sodii bicarbonatis . . . 1 oz.
* * * *

R

(ii) Bacteriophage (Shillong) onc box.
* * * *

R

(iii) Sodii sulphatis . . . ʒi
Magnesii sulphatis . . . ʒi
Tincturæ belladonnæ . . . ℥v
Tincturæ cardamatis co. . . ℥xv
Glycerini . . . ʒi
Aquam . . . ad ʒi
Mitte ʒvi
Sig.

'The red mixture'.

Take two tablespoonfuls as directed, followed by a large glass of water.

R

(iv) Kaylene 2 oz.
Sig.

Label.

The second sheet of instructions is written out fully in every case, for example :—

To-day.

Take a dose of the red medicine (iii), followed by a large glass of water.

One hour later take another dose.

One hour later take two teaspoonfuls of Kaylene in half a glass of water and repeat every two hours until the pain ceases.

Continue during the night if necessary.

Diet.

Clear soup, Bovril or Brand's essence, tea, orange juice, malted milk and perhaps an egg-flip in the evening.

To-morrow.

On waking (or better state a time, say)

7 a.m. Take a level small teaspoonful of bicarbonate of soda in half a glass of water.

7-5 a.m. Take the contents of one tube of bacteriophage in half a glass of water.

7-30 a.m. Take another tube of phage.

8 a.m. Take another tube of phage.

8-30 a.m. Take another tube.

9 a.m. Take another tube.

Wait for *one hour* before taking *anything* else except plain boiled water.

Then take an egg-flip (one egg beaten up in a glass of boiled milk or Horlick's, to which a teaspoonful of sugar may be added). No alcohol.

Diet.

As for yesterday, *plus* clear, strained soup, plain packet or calves-foot jelly. Egg custard. A little toast or cream cracker biscuits.

Save the last stool for the doctor.

One usually sees the patient first in the earlier half of the day, and, if so, it is valuable to see him again in the evening. If the symptoms are severe a plain saline bowel wash of three pints is given, and half an hour later—when the bowel has had time to settle down—the contents of five tubes of bacteriophage in ten ounces of water are run in slowly per rectum and the patient instructed to retain it as long as possible.

Only in infants do I think it worth while giving phage on the first day by mouth.

The patient is seen on the second day, if convenient, in the middle of the day, namely after the phage treatment has been completed. There is usually an early morning stool to be seen, but quite commonly no stool is passed after two or three doses of phage have been taken. Each stool is passed into a receptacle which is emptied before another is passed; in this way the physician is able to see the last stool.

The symptoms are usually relieved after the phage administration and instructions are given for the taking of one dose of the 'red medicine' on waking on the following day, and that the stool be saved.

Thus the patient is again seen on the third day, advisably early in the morning so that the stool does not have to be kept any longer than necessary. This stool is commonly free from any visible blood, pus, or even mucus, in which case the diet may be materially increased to include boiled fish, eggs cooked in any manner, fruit fools, mashed and sieved vegetables and soft puddings, *i.e.*, practically a residue-free diet. Also instructions are given that on the next day (the fourth day of treatment) three doses of phage are to be taken after bicarbonate of soda exactly on the same scheme as before, *i.e.*, bicarbonate on a night-long empty stomach and no food until one hour after the last phage.

If there is still blood and mucus on the second and third days I usually continue the Kaylene three or four times daily, one hour before food. The diet is not increased and on the fourth day a complete course of five doses of phage is repeated instead of three.

On the fifth day the saline mixture is repeated first thing in the morning, as, when the phage is effective, constipation is the usual rule.

The patient may be allowed to report on this stool himself, if the course of the case has been 'normal'. He is instructed to report any kind of relapse and to watch his stools for a further week.

If there is persistence of blood and mucus after the second course of phage, a fresh stool should certainly be sent for examination—if the case has not already been reported as one of amebiasis.

Discussion

It will be noticed that the principle of this treatment is first the flushing out of the bowel with a saline purge, followed by the administration of bacteriophage in successive doses into the washed bowel, after ensuring that the normal acidity of the stomach has been neutralized. Another important point is that the patient is allowed more food than is usual.

Let me take the points in treatment as they arise.

I would emphasize the necessity of writing down fully all instructions. The time table is very useful as the patient can check off each dose as it is taken. He does not have to depend upon his memory and is protected from the interference of solicitous friends.

The 'red mixture' is designed to give a maximum flushing action carrying the water through the bowel and producing a flow of lymph into the bowel.

If phage is as effective as it is said to be, why not give it at once? My answer to this is, simply, it does not work so well. I have been using this treatment for some six or seven years

and have come to the conclusion that I cannot gain anything that first day by administering the phage on an unwashed bowel. Even if I have seen the patient early in the morning or he has had no food for eight or more hours I have found that I only get my maximum phage action after the administration of a dose of salts, or the washing out of the bowel. One gets the impression that the action of the phage is lost on being absorbed into intestinal debris. Kaolin does not seem to affect its activity.

Often the patient is passing small blobs of blood and mucus when first seen and it is not until salts are administered that the bowel's faecal contents are removed.

The phage is given in successive doses over a period of two hours in an attempt to ensure its contact with the whole of the affected bowel. There can be no doubt of the action of phage *in vitro*, and my approach to the question has been through considering it as a frail stuff easily destroyed and lost. It is fortunate that there appears to be no limit to the amount that may be administered. The only untoward symptom that I have met was a sensation of dizziness complained of by one nervous female patient. It normally produces a hungry empty feeling, almost pleasant.

In infants, where the diet contains practically no roughage, I find I can begin the phage treatment on the first day, and give one tube in a tablespoonful of water one hour before each four-hourly feed, starting three hours after a dose of milk of magnesia. The magnesia is repeated at night and five doses of phage given in the early morning as described, but at fifteen-minute intervals. The first-day feeds are of whey, albumin or glucose water and after the full morning phage treatment has been taken a fuller diet of skimmed milk or Sprulac is allowed. A small rectal wash with rectal phage is very useful at the beginning of a severe case.

The diet throughout is designed to limit residue, and carbohydrates are restricted, but allowed in sufficient amount to avoid acidosis. I am sure that it is important to maintain the strength of the patient and thereby increase his resistance, and feel that this is particularly true of infants. It is very gratifying to find that one has steered an infant through a severe Flexner infection without any loss of weight at the next weekly weighing.

One further point I would like to emphasize is that if bacteriophage, given as described, does not produce a cure after the second course, definitely suspect an amoebic infection.

In conclusion, the essential points of the scheme of treatment may be summarized thus:—

- (1) A clean bowel.
- (2) Massive phage dosage to ensure contact with the bowel.
- (3) Residue-less diet to maintain strength.
- (4) Ensuring that the patient understands and carries out the details of the treatment.

HERPES ZOSTER.

EXPERIMENTS WITH TISSUE LYSATE AS A THERAPEUTIC AGENT

By P. A. MAPLESTONE, D.S.O., D.Sc., M.B., Ch.B., D.T.M.
and

L. M. GHOSH, M.B., D.T.M.

(Department of Dermatology, School of Tropical Medicine, Calcutta)

HERPES ZOSTER is characterized by pain and the appearance on the skin of groups of vesicles on an erythematous base along the distribution of nerves from one or more posterior root ganglia. From the aetiological point of view it will suffice to state that the causative organism is a filter-passing virus. This has been definitely confirmed by animal inoculations. Herpes zoster is an important disease from the public health point of view, the causative organism being identical with, or very closely allied to, the virus of chicken-pox and epidemic encephalitis. Instances are not rare where exposures to infection of herpes have been the only possible source of an epidemic of chicken-pox in the family.

Not only is herpes zoster a very painful disease during all its stages, but when the Gasserian ganglion is affected it may involve the eye and it has been responsible for the loss of many eyes. Herpes in the ear is very acutely painful and sometimes causes impairment of hearing.

Immunity.—Much work has been done with the object of producing immunity. The disease has been produced experimentally in laboratory animals and in chicken embryos. Killed virus from these experimental animals is said to confer a certain amount of immunity on lower animals and men. Serum from convalescent patients has been successfully used to protect human beings from herpes and chicken-pox.

Therapeutics.—Various forms of treatment have been advocated, some to relieve the severe pain, and some to diminish the period of suffering or to prevent complications. Sodium iodide by mouth, pituitary extract injections, ultra-violet ray therapy, etc., have been tried without much benefit.

Treatment with killed virus.—We have treated 40 cases with injections of killed virus obtained direct from the herpetic lesions and used in the form of a tissue lysate, the preparation of which is described below. The results have been uniformly successful.

We claim that the killed virus, as we have used it, not only cuts down the duration of the disease but also relieves the pain after the first

(Continued from previous column)

It is only fair to add that most of the points in this treatment were evolved as a result of discussion on bacteriophage with Colonel Morison when he was at the Pasteur Institute in Shillong.

or second injection, and in no case was there any complication from the disease. Altogether two or three injections are required to complete the course of treatment and it takes only one week. The technique of preparing the tissue lysate is a simple one and can be carried out in any bacteriological laboratory.

The question now arises as to the practical application of the therapy in general practice.

and ether in equal parts. With a pair of sharp scissors, curved on the flat, two or three vesicles are removed carefully so that no normal tissue is included in the portion cut off. A known weight (20 mgm. are generally taken) of the tissue is ground up in a sterile agate mortar with sterile pumice-stone powder until it forms a uniform emulsion with sterile normal saline solution. The amount of saline used for 20

TABLE
Protocols of cases treated and cured by injection of tissue lysate

23	H.	M.	30	4 days	0.1
24	M.	F. Ch.	5	4 "	0.1, 0.2	2 days.
25	H.	M.	37	6 "	0.1, 0.2	2 "
26	H.	M.	25	3 "	0.2, 0.2, 0.2	Alternate days.
27	H.	F.	17	2 "	0.2, 0.2	" "
28	H.	F.	15	4 "	0.2, 0.2	" "
29	E.	F.	36	3 "	0.2, 0.2, 0.2	" "
30	H.	M.	28	2 "	0.2, 0.2	" "
31	H.	M.	27	1 week	0.2
32	H.	F.	35	5 days	0.2
33	H.	M.	21	4 "	0.2
34	H.	M.	14	1 week	0.2
35	H.	M.	22	1 "	0.2
36	M.	F.	70	5 days	0.2
37	H.	M.	20	1 week	0.2
38	H.	M.	30	3 days	0.2
39	H.	F.	45	2 "	0.2
40	H.	M.	60	4 "	0.2

Footnote.—(1) Some of the early cases, cases 1, 2, 3 and 5, had four injections but it was soon found that two to three injections were sufficient.
(2) Cases 31 to 40 were given only one injection each. All of them improved so rapidly that no further injections were necessary.

The possibilities are not remote and the difficulties are not many to overcome in order to make the killed virus available to practitioners. As previously stated, the disease has been produced in laboratory animals, and chicken embryos take the infection. From these sources there need be no dearth in the supply of virus.

Preparation of tissue lysate.—A few herpetic vesicles are sterilized by application of alcohol

mgm. of tissue is 20 c.cm. This mixture is then filtered, first through a Kieselghur filter and afterwards through Chamberland candle No. L3 under negative pressure. (A water pump costing about Re. 1-8 will produce sufficient negative pressure for this purpose.) To the filtrate add an equal quantity of normal saline containing 0.2 per cent of commercial formaldehyde.

(Continued at foot of next page)

REGIONAL ILEITIS

By V. M. KAIKINI, B.A., F.R.C.S. (Edin.)

*Surgeon, King Edward Memorial Hospital, Bombay;
Consulting Surgeon, Y. Nair Hospital, Bombay*

REGIONAL ILEITIS is a disease discovered very recently and the pathological conditions due to this disease were treated as malignant, tuberculous or even actinomycotic.

In 1932 Crohn, Ginzburg and Oppenheimer, segregated from the miscellaneous group of benign granulomas a necrotizing and cicatrizing inflammation, confined to the terminal ileum, which they believed to be a pathological entity and called it regional ileitis. Crohn also described the condition and classified it into four groups. In the early stages the symptoms resemble those of appendicitis to such an extent that innocent appendices are often removed, while the real source of discomfort is overlooked.

This is a disease pre-eminently of young adults, and runs a very chronic course. This condition is found not only in the ileum, but also in the other parts of the small bowel and the large intestine. But in the majority of cases, the disease begins at the ileo-cæcal valve and spreads to the lower portion of the ileum. The disease described as 'non-specific granu-

(Continued from previous page)

This is then put into a rubber-capped sterile phial and tested for sterility, and if found free from bacterial contamination it is ready for use. The resultant dilution comes to 2 c.cm. per mg. of the diseased tissue. The initial dose for an adult is 0.1 to 0.2 c.cm., and it is not necessary to increase the dose beyond 0.2 c.cm. Injections are given intradermally every other day or every third day. Usually only two or three injections are required for a full course of treatment.

Summary

Herpes zoster is an important disease from the public health point of view as the causative organism is identical with, or very closely allied to, the virus of chicken-pox and epidemic encephalitis. It is a very painful disease. It is responsible for the loss of many eyes when it affects the ophthalmic branch of the 5th nerve. Much work has been done from the immunological point of view. Various forms of treatment have been tried but none with much benefit.

Forty cases have been treated with intradermal injections of tissue lysate prepared from the herpetic vesicles and the results have been uniformly successful in relieving the pain and cutting down the duration of the disease. The technique of preparation of tissue lysate is simple and it would be possible to prepare it on a commercial scale.

loma of the ileo-cæcal region' is identical with regional ileitis.

Ætiology

The ætiology is very obscure. The appendix has been held responsible by Hormans. He maintains that the vascular relations of the appendix are more favourable to ileal than to cæcal involvement. It is possible that some peculiarity of the anatomy of the terminal ileum, its mesentery and its blood supply, may predispose toward the development of chronic granulomatous inflammation in this region. The arrangement which would permit of the twisting angulation, and partial intermittent intussusception, or volvulus, has been considered by Crohn, Ginzburg and Oppenheimer as a factor which plays an important rôle in the disturbance of vascular mechanism which later on leads to the development of non-specific granuloma. They refer particularly to the repeated and self-reducing intussusception or recurrent partial volvulus at the ileo-cæcal valve, and emphasize the inability of differentiating in the end stages granulomatous lesions due to primary vascular insufficiency from those due to primary infectious agents. The abrupt cessation of the primary inflammatory process, giving rise to an organic stricture at the ileo-cæcal valve in many cases, could be explained on the basis of recurring self-reducing intussusception. According to Batson, the ascending branch of the ileo-cæcal artery which supplies the cæcum is more or less fixed in most cases, whereas the terminal branch of the same artery which supplies the terminal segment is capable of considerable rotation. It is conceivable that an unusual mobility of the terminal ileal segment might, by pinching or twisting the terminal branch of this artery, tend to devitalize the part in much the same way as an intussusception. As the disease seems most advanced at the ileo-cæcal valve, primary neuromuscular abnormality here might act as a predisposing factor inducing ileal stasis, infection, infiltration, and finally obstruction. The lymphangitis and surrounding inflammation, in chronic inflammatory lesions of the appendix, might encroach upon and infect the blood supply, and in this way slowly devitalize this segment of ileum, producing a lesion like that of terminal ileitis.

Pathology

In the fully developed case the 10 to 12 of the terminal inches of the ileum ending at the ileo-cæcal valve are thick, boggy and oedematous. The serosa is of a blotchy red colour and the mesentery of the involved segment is thickened and fibrotic and contains numerous enlarged glands. The lesion apparently begins at the ileo-cæcal valve and gradually tapers off as it ascends the ileum proximally. Oval mucosal ulcers about one centimetre in diameter are found in some cases occupying the long axis

PLATE VI

Fig. 1.—Case 1. Loop of the ileum inflamed and congested, with enlargement of the mesenteric glands. The local appearance and the clinical symptoms tallied exactly with the first of the four groups, into which Crohn has divided the clinical types in regional ileitis.

Fig. 2.—Case 4. Terminal ileum indurated and enormously dilated. The portion of the ileum at the ileo-cæcal junction is constricted on account of strictures due to chronic inflammation and fibrosis. The cæcum also is found to be slightly involved in the inflammation. The involvement of the mesenteric glands is also shown. The hose-like appearance of the dilated ileum is characteristic.

of the mesenteric border. The mucosa is the seat of diffuse destructive ulcerative process. The remaining coats of the bowel are markedly thickened from inflammatory hyperplasia, giving the involved segment a hose-like structure. (This was markedly seen in one of the cases quoted below, no. 4.) The fully developed cases show a marked stenosis of the lumen and frequently walled-off abscesses, and perforations with resultant fistulæ which may extend into the colon. Perforation into the mesentery with the development of a walled-off abscess may give rise to peri-cæcal and peri-appendical adhesions and thickenings, giving the roentgenological appearance of hyperplastic tuberculosis. Usually there is some fluid in the peritoneal cavity, and the peritoneal surfaces are moderately hyperæmic and frequently present a granular appearance simulating slightly the lesions of miliary tuberculosis.

Microscopically the process resembles a low-grade inflammatory reaction characterized by an enormous widespread œdema with a mild cellular reaction, showing lymphocytes, plasma cells, monocytes and a few eosinophiles.

In the acute stage the diseased intestines may appear œdematous, hyperæmic or congested, and of a maroon colour. The mesentery may or may not be thickened and œdematous.

Although the disease is mostly found in the terminal ileum it may occur in the cæcum and the large bowel.

Clinical features

Crohn divides the disease into four clinical types:—

(1) The symptoms of this group simulate those of acute intra-abdominal inflammation, appendicitis in particular. Pain and tenderness in the right lower quadrant, accompanied by cramps, fever and leucocytosis occur; there may or may not be a palpable mass. Operation reveals a greatly thickened and reddened terminal ileum, which has a tendency to bleed. The mesentery is œdematous with enlarged hyperplastic glands. The appendix may be involved by contiguity, but it shows no mucosal inflammation.

(2) Symptoms suggestive of ulcerative colitis occur in this stage with diarrhœa and cramp-like abdominal pains with blood and mucus in the stools occasionally. Severe anæmia may develop with marked loss of weight malaise and slight fever.

(3) In this group the stenotic stage follows the ulcerative. As a result extensive thickening of the intestinal wall giving rise to constriction and later on to obliteration, due to healing of the mucosal ulceration, is found. This is most marked in the region of the ileo-cæcal valve. The symptoms are those of partial obstruction of the small intestine. A mass is usually palpable. Violent cramps, occasional attacks of vomiting and constipation occur.

(4) In this stage multiple fistulæ are formed that may open either internally or externally, through the abdominal wall. Roentgenological examination may reveal these fistulæ which persist and resist surgical measures at closure, unless the bowel is resected.

The symptoms depend upon the location of the lesion. The higher the constriction the more pronounced are the symptoms of a high intestinal obstruction. The extent and severity of the lesions determine the predominant symptoms. The most typical cases are those of young adults who give a history of severe colic-like pains in the abdomen, occurring usually two to three hours after eating, with nausea and vomiting. The pain in these cases is intermittent and yet severe enough to require morphine. Visible peristalsis may be observed.

Although the disease is mostly found in the last portion of the ileum, the cæcum and the ascending colon are also found to be affected. In the cases quoted below, the cæcum was found affected as much as the lower portion of the ileum and in a couple of cases was the only organ affected.

In early stages, the radiogram shows obstruction of the terminal ileum without evidence of an intrinsic lesion in the cæcum. Other signs are: (a) the string sign in the terminal ileum which is similar to that already described by Crane, as occurring in the colon in mucous colitis; (b) filling defect proximal to the cæcum; (c) an abnormal contour of the last filled loop of the ileum; and (d) dilatation of the ilcal loops proximal to the obstruction (Kanton). Reflex colonic spasm may be found to occur with contracture of the cæco-colon, but more likely of the cæcum proper.

An actual defect on the mesial aspect of the cæcum may be due to adhesions or fistulæ from the diseased ileum.

The course of the disease is very insidious. In the beginning the clinical features resemble chronic ulcerative colitis-diarrhœa, but without tenesmus and a little blood, lower abdominal pain, fever, continuous loss of weight and anæmia. As the lesion begins to cause obstruction, attacks of abdominal pain, especially in the lower right quadrant, increased peristalsis and vomiting occur. Fistulous tracks may be responsible for localizing symptoms elsewhere in the abdomen. The outstanding physical findings are: (1) a mass in the right iliac region; (2) evidence of fistula formation; (3) emaciation and anæmia; (4) a scar of previous appendicectomy; and (5) evidence of intestinal obstruction.

The disease runs a very slow course and it takes a couple of years to develop symptoms of obstruction. The age range is between 15 and 56 years.

Differential diagnosis

The lesion may be mistaken for appendicitis, ileo-cæcal tuberculosis, ulcerative colitis, lymphosarcoma, actinomycosis or carcinoma. The

diagnosis of regional ileitis is suggested when one encounters in an adolescent or a young adult the symptoms of chronic obstruction of the small intestines accompanied by signs of a low-grade

lower quadrant or palpable *per rectum*. Usually there is a history of irregular constipation alternating with diarrhoea. Mucus and at times blood may be present in the stools.

Fig. 3.

Fig. 4.

Fig. 5.

Figs. 3, 4 and 5.—Roentgenograms of case 4, showing well-marked dilatation of the ileum above the ileo-caecal junction.

inflammatory process like mild fever, slight leucocytosis, loss of weight, a variable degree of anaemia and a somewhat tender mass in the right

Roentgenography is of great help. As a rule regional ileitis begins with acute symptoms like recurring diarrhoea, with severe abdominal pains,

which never occur in the case of either tuberculosis or malignancy. The course of the disease is much more prolonged in regional ileitis than in the other two diseases.

Treatment

In the early stages, as the disease is not properly diagnosed, the treatment is only symptomatic. After the lesion is fairly advanced with symptoms of obstruction, short-circuiting gives very good results. Resection need not be done except under special circumstances, such as presence of fistulae, etc.

Below are given the histories of five cases which were at first diagnosed as either appendicitis, tuberculoma, or carcinoma, but from the history, gross appearance and pathological examination were found to be cases of regional ileitis.

Case 1.—Female, aged 19. Admitted in August 1933 for pain and swelling on the left side of the abdomen near the umbilicus. For the last three years she had been getting fever off and on, and dull pain round about the umbilicus which increased after food. The severe pain started about eight days previously all over the abdomen but more marked at the umbilicus and the right iliac fossa. When seen, a swelling was felt a little to the left of the umbilicus, very tender and boggy. Radiogram with barium enema did not show any abnormality in the colon or caecum. It was provisionally diagnosed as a case of appendicitis.

On opening the abdomen the peritoneum gave evidence of recent inflammation. The uterus was small and undeveloped. Appendix looked slightly inflamed, and was removed. Caecum looked quite normal. The small intestine about 12 inches away from the ileo-caecal valve was found red and inflamed, covered with flakes of yellow organized lymph, and forming a loop of about eight inches with the great omentum firmly adherent to it. There were a good many enlarged glands in the mesentery, closely connected with the inflamed loop. From the appearance of the intestine, especially on account of the presence of the enlarged glands, it was taken for granted that the lesion was tuberculous. About ten inches of the ileum including the affected part were excised and lateral anastomosis was done. The patient made a good recovery and was discharged in good condition.

From the three years' history of abdominal pain, the lesion being localized to a portion of the lower ileum, the acute and subacute inflammatory reaction in the intestine, and the chronic inflammatory character of the glands, without evidence of caseation there is every reason to think that it was a case of regional ileitis, occurring in the small intestine a little more to the proximal side of the ileo-caecal valve than is usually found (plate VI, figure 1). This case corresponds to the type 1 described by Crohn.

Case 2.—Male, aged 50, admitted in July 1935 for pain in right iliac fossa, and a tumour in the caecal region. History of chronic pain in the right iliac fossa for some time. Diagnosed as a case of tuberculous caecum. On opening the abdomen the caecum was found to be thickened and inflamed. The ileum was not much affected. A large number of enlarged glands was found in the mesentery round about the ileo-caecal junction. The ileum was divided about eight inches above the ileo-caecal valve, and lateral ileo-colostomy done. A couple of enlarged glands were removed and on pathological examination were found to be ordinary inflammatory glands, without any evidence of tuberculous lesion. (Follicular hyperplasia as a result of simple chronic inflammation. No evidence of tuberculosis or malignancy.)

So this must have been a case of regional ileitis occurring in the caecum without much evidence of the disease in the lower ileum.

Case 3.—Male, admitted for symptoms of vague abdominal pain with history of constipation. A hard irregular mass felt on the right side of the abdomen lateral to the umbilicus. On opening the abdomen a hard irregular round tumour of the size of a golf ball was seen about the middle of the ascending colon. Glands were found to be enlarged in the mesentery. Ileo-colostomy was done. The appearance of the lesion was not of the hypertrophic type that is usually seen in the tuberculous lesions of the caecum and the ascending colon. Moreover, tuberculous lesions, especially independent of the caecum, are rare in the ascending colon. So most probably it was a case of regional ileitis occurring in the ascending colon. The glands were not examined pathologically.

Case 4.—Male, aged 40, public worker. In 1921 he had to do a good deal of travelling in villages for social and political work, and had to be irregular as regards his meals, etc., living on milk diet which gave rise to flatulence. After that his health improved a bit but complaint of dyspepsia continued. He kept fairly good health in other respects till 1935.

In October 1935, at about ten o'clock in the morning one day he got severe abdominal pain with constipation and vomiting. Bowels worked after enema and pain stopped. The same thing—abdominal pain constipation, etc.—happened about a month later. These attacks now recurred every fifteen days and his weight began to decrease. On 5th January, 1936, he got a similar attack, but the abdominal pain did not disappear even after taking an enema and he felt severe borborygmi in the abdomen. He consulted a physician who advised him to stop taking rice and prescribed a special diet, with emetine injections. Gradually he started getting rigidity of the abdominal muscles on the right side along with pain in the part which made one suspect appendicitis.

He started taking liquid paraffin and olive oil for his constipation. Once he took a dose of santalin, ascribing the pain to worms. On 10th February, 1938, he got an enlargement of the right scrotum which subsided after about four days with local applications. From 27th February he started getting low fever, and was advised complete rest, and gold 'Bhasma' (calined metallic gold) by mouth. This brought on some improvement in his health which was maintained till the end of August 1936. Then again he started getting abdominal pain with vomiting, so he changed his diet and lived only on soup and bread, which improved his condition a little, and he maintained fairly good health till January 1937. But again he started the old trouble of abdominal pain and constipation, and lost about 30 pounds in weight. When seen in June 1937, he was very much emaciated and his weight which was originally 137 pounds had come down to 93 pounds. Practically he was skin and bone. He complained of severe constipation with abdominal pain soon after food. On inspection movements of the intestine could be seen. The abdomen was slightly distended in the lower part and the abdominal wall was doughy to the feel. Apparently everything pointed to the existence of chronic obstruction in the small intestines, so the case was diagnosed as chronic intestinal obstruction, due to a tuberculous lesion situated most probably at the ileo-caecal junction. A skiagram was taken which showed narrowing at the ileo-caecal junction and an enormous dilatation of the lower ileum above the stricture. As the condition of the patient was very low about 300 c.cm. of blood were transfused which greatly improved his general condition and operation was done one week later.

On opening the abdomen the peritoneal cavity was found to contain a little serous fluid. The caecum was found to be thickened and inflamed. The lower part of the ileum up to about eight inches from the ileo-caecal valve was found to be narrowed and fibrosed, and contained in two places—at the ileo-caecal junction and about seven inches above it—localized areas of

thickening, indicating strictures. A good many glands were found enlarged in the mesentery at the ileo-cæcal junction. The ileum proximal to it to the extent of about 18 inches was thickened and enormously dilated (resembling a hose), devoid of normal lustre and of a dull grey colour. As the lesion was at first supposed to be tuberculous, the dilatation was ascribed to the stricture. Ileo-colostomy was done by anastomosing the portion of the dilated ileum about eight inches from where the dilatation began to the middle of the transverse colon. The convalescence was very smooth and the condition of the patient began to improve very steadily. The symptoms of obstruction disappeared and the patient started taking normal diet from the 15th day. His weight which was 84 pounds on 5th August, 1937, became 90 pounds on 15th August, 1937, and 115 pounds on 5th September, 1937. At present he is taking his normal diet, getting regular motions, and is free from all symptoms of obstruction like abdominal pain, hiccorygmi and vomiting. Appetite is good and he is getting his normal energy back.

This is a very typical case of regional ileitis with all the pathological characteristics and clinical symptoms of the disease. It is significant that although the dilated portion of the ileum which indicated chronic inflammation was anastomosed to the colon nothing untoward happened.

Case 5.—K. S. M., aged 35, admitted for pain in the epigastrium and round about the umbilicus. Tenderness most marked in the right iliac fossa. The trouble first began about six years ago, with pain in the lower abdomen, immediately after food, which increased gradually. He suffered from diarrhoea with mucus about five years ago.

When seen the patient was fairly well built and not much emaciated, and complained of loss of appetite and abdominal pain after food, most marked in the epigastrium. Well-marked tenderness in the appendicular region. A diagnosis of appendicitis was made. On opening the abdomen the cæcum was found to be slightly thickened and congested indicating chronic inflammation, but not showing the intramural hypertrophy typical of a tuberculous lesion. A group of enlarged glands was found in the mesentery at the ileo-cæcal junction. The ileum appeared quite normal. It was divided about eight inches from the ileo-cæcal junction and ileo-colostomy was done. The condition of the patient improved steadily.

The long history of the disease with acute attacks of colitis and the gross appearance of the cæcum with enlarged non-inflammatory glands are in favour of the case being one of regional ileitis. This is an atypical case where the lesion occurred in the cæcum, without involvement of the lower ileum.

Out of these, case 4 was the most typical case of regional ileitis; especially the naked-eye hose-like appearance of the intestines was exactly like what is described by Crohn. Case 1 came with symptoms of acute exacerbation and was operated on soon after the acute attack subsided. Here the lesion was localized to the ileum, some distance away from the ileo-cæcal valve. In cases 2 and 5 the lesion was confined only to the cæcum and a small portion of the ascending colon, the ileum being completely free. The naked-eye appearance was not at all like that usually seen in a tuberculous cæcum. Moreover the pathological examination of the enlarged glands, especially in one case, excluded tuberculous lesion.

About case 3, the lesion was not very typical of regional ileitis. But it had not the characteristic appearance of a tuberculous lesion either. The long history without any well-marked

THE TREATMENT OF SPLENOMEGALY BY INJECTIONS OF MILK

By C. L. PASRICHA,

MAJOR, I.M.S.

and

G. S. CHOPRA, M.B., B.S.

(From the Department of Bacteriology, Calcutta School of Tropical Medicine)

SINGH (1932) reported favourable results following the injection of milk intramuscularly in patients suffering from splenomegaly, more particularly when the enlargement of the spleen

(Continued from previous column)

obstructive symptoms or any secondaries was against malignancy. The whole appearance indicated a chronic inflammatory condition. So there is reason to think that it might have been an atypical case of regional ileitis occurring in the middle of the ascending colon.

Summary

1. Regional ileitis is a fairly common disease, and is often diagnosed as a tuberculous, a malignant, or an appendicular lesion.
2. The commonest site of the lesion is the lower eight to ten inches of the ileum. But it may occur in the cæcum, colon, or the ileum away from the ileo-cæcal junction.
3. Enlargement of the glands showing pure inflammatory reaction is an important diagnostic sign.
4. Dilatation of the intestine above the stricture with fibrosis and thickening giving the affected part a hose-like appearance is a characteristic feature of this disease.
5. The important symptoms are pain, often severe and cramp-like, diarrhoea, vomiting, fever and loss of weight with symptoms of chronic obstruction.
6. The x-ray picture is a filling defect in the terminal ileum, dilatation of the intestine proximal to the defect, and the characteristic string sign.
7. Resection or ileo-colostomy gives good results. Resection should not be done when the patient's condition is low, as the mortality may be high.
8. Many cases where persistent recurrence of pain occurs after removal of the appendix may be cases of regional ileitis which were wrongly diagnosed as appendicitis.

was malarial in origin. Enlarged spleens which reached nearly to the umbilicus disappeared under the costal margin after three or four or at the most five injections of milk. In 1934 this method of non-specific therapy was started in the out-patient department of the Carmichael Hospital for Tropical Diseases. The patients selected for treatment were those with markedly enlarged spleens extending to the umbilicus or lower who gave no history of kala-azar and whose sera were negative both to Chopra's test and Napier's test for this disease. These patients had been under observation prior to the beginning of milk injections for at least three months, during which period the usual forms of medical treatment had been given without producing any appreciable effect on the size of the spleen. All the cases were afebrile, blood smears showed no parasites and in the majority there was a varying degree of anaemia. In view of the pressure of routine work in an out-patient department it was not possible to make complete investigations of each patient.

Skimmed fresh milk was sterilized on three consecutive days in required amounts in test-tubes. The milk was tinged lightly with phenol

Careful records were made of the size of the spleen, of the general symptoms and of any reactions following the injections. During the course of treatment no other medication was given.

The patients selected were 94 male adults and 6 female adults of the labouring class. The treatment by the injection of milk was popular and no difficulty was experienced in securing regular attendance of the patients. In fact the only difficulty was the extreme disappointment of those patients in whom there was no diminution in the size of the spleen and no marked improvement in the symptoms. In the majority of the patients in whom satisfactory results were obtained marked improvement was noted usually after the sixth or seventh injection. A certain number of the patients in whom marked shrinkage of the spleen had occurred were kept under observation for periods varying up to a year and no relapse was noted. The patients who did not react to the first series of ten injections failed to show any appreciable effect to further series of milk injections. The results of the treatment are given below in tabular form :—

TABLE I
The results of treatment of the whole series

	By the intra-muscular route	By the intra-cutaneous route
Total number treated	70	30
Improvement noted in	50 or 71.4 per cent	16 or 53.3 per cent
Spleen not palpable after treatment	10 or 14.3 "	4 or 13.3 "
Spleen considerably reduced but still palpable	24 or 34.3 "	10 or 33.3 "
Slight diminution in the size of the spleen but definite improvement in the symptoms.	16 or 22.8 "	2 or 6.6 "
No appreciable difference in the size of the spleen and no improvement in the symptoms.	20 or 28.6 "	14 or 46.7 "

red in order to disguise from the patients the nature of the material injected. It is important that fresh milk from a reliable source be used as otherwise there is an enormous multiplication of bacteria the products of which might lead to undesirable reactions. A generous supply of Aolan was available through the courtesy of the manufacturer's agents and a small series of patients was treated with it. The results were similar to both series but when facilities exist for sterilization, for reasons of economy, milk is to be preferred. The results reported in this paper are those based on the treatment with milk alone.

Of the 100 patients treated 70 were given the milk injections intramuscularly and 30 patients intracutaneously. The dosage was (1) by the intramuscular route, preliminary dose of 4 c.cm. gradually increased to 16 c.cm. at intervals of five to seven days, and (2) by the intracutaneous route, 0.1 to 0.3 c.cm. with a maximum of 0.2 c.cm. at any one site at intervals of five to seven days.

It will be seen that the intramuscular route appears to yield better results but if the figures for those in whom the spleen was considerably reduced are compared there is no appreciable difference in the results obtained by the two methods. In the series treated by the intramuscular route the spleen was markedly reduced in 34 or 48.5 per cent of the patients treated and in patients treated by the intracutaneous route the spleen was reduced in 14 or 46.6 per cent.

The results in table II show that better results were obtained in the patients suffering with enlarged spleens reaching to about the level of the umbilicus than in the patients in whom the spleen was larger. Although the number of patients treated was not sufficiently large the general impression that was formed during the course of this trial was that in patients in whom the spleen was not hard and not sclerosed the shrinkage of the spleen occurred quicker and was complete usually before the end of the series of the ten injections of milk.

TABLE II

The results of treatment according to the size of the spleen prior to treatment

	Spleen up to umbilicus	Spleen below umbilicus
Total number treated	68	32
Improvement noted in	55 or 80.7 per cent	11 or 38 per cent
Spleen not palpable after treatment	12 or 17.6 "	2 or 7 "
Spleen considerably reduced but still palpable	32 or 47.0 "	2 or 7 "
Slight diminution in the size of the spleen but definite improvement in the symptoms.	11 or 16.1 "	7 or 24 "
No appreciable difference in the size of the spleen and no improvement in the symptoms.	13 or 19.3 "	21 or 62 "

Summary.—The results of the treatment of a series of one hundred patients suffering from splenomegaly not of kala-azar origin with injections of skimmed sterilized milk are recorded. The results show that there is a marked reduction in the size of the spleen in approximately 50 per cent of the patients treated.

From the data available the results after the injection of the milk by the intramuscular route are better than the results after the intracutaneous route, probably because of the greater amount of foreign protein injected by the former route.

MODIFIED TECHNIQUE FOR PHRENIC EVULSION

By R. VISWANATHAN, B.A., M.D., M.R.C.P. (Lond.)
Medical College, Vizagapatam

THE most important modification from the ordinary technique adopted for operations on the phrenic nerve is the posture of the patient. He is kept in the sitting posture with slight inclination backwards sufficient to make him comfortable. An adjustable chair, such as a dental chair, is preferable, as in case the patient faints the head can be lowered immediately. The head is kept turned towards the opposite side. It is important that the upper limbs must be hanging down, without the elbows or hands resting anywhere. This simple precaution enables the muscles of the neck to be kept taut.

Four cubic centimetres of a 1 per cent novocaine are all that is ordinarily used for local infiltration of the part, 2 c.cm. for the skin and subcutaneous tissue, 1 c.cm. along the lateral border of the sterno-mastoid and 1 c.cm. underneath the deep fascia covering the scalenus anterior.

An incision 1 inch in length is made, parallel to and $1\frac{1}{2}$ inches above the clavicle with the centre of the incision on the lateral border of the sterno-mastoid. As the scalenus anterior can be easily palpated when the patient is in this posture the incision can be made to cover the whole breadth of that muscle. The incision

can be deepened to involve the skin, subcutaneous tissue and platysma. The lateral border of the sterno-mastoid is defined and retracted medially. The position of the scalenus anterior is made sure by the palpating finger, and the fascia covering it is separated by blunt dissection. The pad of fat underlying it is also separated in the same way. The nerve is found to lie on the scalenus anterior crossing it from the lateral to the medial side.

Further procedure is the same as in the usual technique. I have successfully adopted this technique in 93 cases.

A Mirror of Hospital Practice

TYPHOID FEVER PRESENTING SOME UNUSUAL FEATURES

By P. V. KARAMCHANDANI

MAJOR, I.M.S.

and

C. B. MILLER

CAPTAIN, I.M.S.

Jamsetjee Jeejeebhoy Hospital, Bombay

K. P. A., a Hindu male, aged 25, arrived in a military station for training on 3rd February, 1937, from his village five miles away. On the same day he was inoculated with 1 c.cm. of T.A.B. vaccine. After the inoculation he received 48 hours' 'excused duty' and had no complaints.

On the 16th, he reported sick complaining of fever, cough and cold. He said he had been having fever for three days with abdominal pain at night. On examination his temperature was 99°F., pulse 86, respiration 22. His tongue was clean and no abnormal physical signs were present anywhere. His blood for malaria was negative. On the 17th evening his temperature was 102°F. having risen steadily without remissions, pulse 100, respiration 26. His bowels moved for the first time that evening since reporting sick.

On the 19th he was admitted to the hospital. That morning his temperature was 102.2°F., pulse 80, regular, volume and tension good. The tongue was clean and moist anteriorly, but furred posteriorly; throat congested, abdomen retracted, liver and spleen not palpable. Nothing abnormal was detected in other systems nor in the urine or stools. Leucocyte count showed total white blood corpuscles—6,800 per mm., polymorphonuclears—60 per cent, lymphocytes—35 per cent, large mononuclears—3 per cent, eosinophils—2 per cent. No parasites were found.

Widal reactions.—

	21st February	25th February	1st March	6th March	21st March
<i>Bact. typhosus</i> ..	0	+ 1/175	+ 1/175	+ 1/175	+ 1/400
<i>Bact. paratyphosus A</i> ..	0	+ 1/125	+ 1/125	+ 1/35	+ 1/35
<i>Bact. paratyphosus B</i> ..	0	+ 1/125	+ 1/50	+ 1/35	+ 1/25
<i>Bact. typhosus O</i> ..	+ 1/25	+ 1/125	+ 1/250	+ 1/250	+ 1/175
<i>Bact. paratyphosus AO</i> ..	0	0	0	0	0
<i>Bact. paratyphosus BO</i> ..	0	+ 1/25	+ 1/25	+ 1/25	0

On the 21st and 22nd, i.e., on the 6th and 7th days of the illness his temperature was normal at noon, rising to 100°F. and 101.4°F. in the respective evenings. His general condition remained good. He was given 0.3 gm. metarsenobillon subcutaneously; this caused no change in his condition.

On the 26th (11th day) he passed a stool at 2 a.m. containing about 6 ounces of altered blood; his temperature fell to normal at noon for four hours, rising in the evening to 99.4°F. That day he had five meænic stools. He was put on calcium lactate, tincture of opium and quinine and had no more motions for 48 hours.

From the 27th (12th day) onwards the fever was continuous but gradually came down by lysis. On 9th March, being tired of the restricted diet he took some solid food from another patient and promptly got a relapse. It lasted 29 days and the temperature reached 104°F. on two occasions. There were no complications.

After the 51st day he had no more fever and was discharged on 28th April.

Laboratory findings.

Bact. typhosus was isolated on blood culture taken on 22nd February, 1937.

This case raises several points for discussion :

1. The average incubation period of typhoid fever is 10 to 14 days. This patient was inoculated on 3rd February and the first sign of illness did not appear till the 13th. Does this mean that inoculation during the incubation period does not stop the disease ?

2. The course of fever was very unlike that of typhoid. In fact it was a bacteriological rather than a clinical diagnosis. Was such a course of fever due to prophylactic inoculation ?

3. Such a protracted course of illness in spite of prophylactic inoculation is rather unusual.

4. Is it possible that the inoculation itself could have contributed towards the illness ? The lapse of 10 days after the inoculation which coincided with the incubation period was interesting.

malignant disease. About the same time, Proust (1907) in France, and Braun in Germany reported similar experiences. In all their cases,

Fig. 1.—Showing the x-ray picture after a barium enema.

Fig. 2.—Showing the x-ray picture two and a half years after resection of caecum and ascending colon and proximal half of transverse colon and end-to-side anastomosis.

A PSEUDO-MALIGNANT TUMOUR OF THE ILEO-CÆCAL REGION

By M. G. KINI, M.C., M.B., M.Ch. (Orth.), F.R.C.S.E.
Surgeon, King George's Hospital Medical College,
Vizagapatam (S. India)

A TUMOUR in the ileo-cæcal region when it simulates a malignant tumour but is not actually malignant is interesting, as radical operation is undertaken on the presumption that it is malignant. Such pseudo-malignant tumours were reported by Moynihan in his articles entitled 'Mimicry of malignant disease in the large intestine', by Robson in 1908 who pointed out similar inflammatory tumours simulating

their original diagnosis of malignant tumour was supported by classical symptoms of large bowel malignancy, viz, loss of weight, bleeding, colic and obstruction. It was only after operation

and histological study that the inflammatory nature of the tumours was established.

Mock in 1931 reported 10 similar cases, and he believes that the process arises primarily from a gastro-intestinal focus. The major portion of the mass was found in the mesocolon with progressive and secondary infiltration of the gut wall fading into the muscularis mucosæ without any changes in the mucosa itself. He has classified the ætiological factors under the following heads:—

(1) Conditions existing in the gastro-intestinal tract.

(2) Extra-peritoneal infection which spreads to and involves the gastro-intestinal tract.

(3) Traumata due to surgical procedures or extraneous injury.

Case: An emaciated male, aged 60 years, was admitted in 1933 for treatment of acute pain in the right iliac fossa with constipation. He had been operated on for right oblique inguinal hernia one year before. On admission he was markedly emaciated and gave a history of passing of mucus but not of blood in his stools. A tumour in the right iliac fossa was found and an elongated bulging occurred on coughing at the site of the old operation scar. The mass did not move with respiration, it was slightly tender on palpation and its edges could not be defined exactly; the surface of the mass was smooth; consistency firm and on percussion it was dull. Occasionally a distinct bulge could be seen associated with intense colic and discomfort to the patient. A barium meal examination was not done for fear of intestinal obstruction, but a barium enema was given and the picture showed no filling defect in the large bowel. All the other systems were found normal. His systolic blood pressure was 110 mm. and diastolic 70 mm. and so under local anæsthesia (para-abdominal block) the abdomen was opened by a right para-median para-umbilical incision. On opening the abdomen the cæcum was found adherent to the anterior abdominal wall and while freeing it a mass was noticed at the ileo-cæcal junction, with enlarged glands along the ileo-colic vessel. The cæcum and ascending colon were mobilized right up beyond the hepatic flexure and a colectomy was performed including the distal 6 inches of the ileum and the proximal half of the transverse colon. An end-to-side anastomosis of the ileum with the transverse colon was done after closing the cut end of the transverse colon. The posterior abdominal wall was peritonized and the abdomen closed with a drain in the right para-colic gutter through a stab incision one inch in front of the anterior superior iliac spine. A radical operation was undertaken on the presumption that the tumour was malignant. The patient made an uneventful recovery and was discharged cured on the 14th day after the operation. The specimen after removal proved to be non-malignant.

His case has been followed up to date and he is keeping perfect health and the end-to-side anastomosis is functioning well as shown in the figure.

Pathological appearances of tumour

Macroscopic.—Marked thickening of the wall of the cæcum: ileo-cæcal angle shows marked thickening with enlargement of glands and a small abscess cavity was found in this thickened mass. The mucous membrane of the cæcum was found to be normal in its entire extent.

Microscopic.—All the layers of the cæcum are found to be normal, but outside this there is an area of dense fibrous tissue showing a few foci of round-cell infiltration with chronic inflammatory tissue.

This case illustrates a pseudo-malignant tumour due to traumatic cause after surgical procedure, viz, operation for right inguinal hernia, as suggested by Mock.

A CASE OF JEJUNAL DIVERTICULOSIS

By VISHWA NATH, M.A., M.D., F.R.C.P.I.,

D.P.H., D.T.M. & H.

Department of Pathology, King Edward Medical College, Lahore

SURJU, M. M., aged 60 years, was admitted into the Mayo Hospital for enlarged prostate, and died two days after prostatectomy.

Post-mortem examination showed marked thickening of the wall of the urinary bladder. Kidneys showed marked pallor of the cortex with greyish streaks and points indicative of ascending pyelo-nephritis.

The jejunum, from a point about one foot from the distal end of the duodenum, showed multiple diverticula for a length of about two feet. The diverticula were twenty-two in number and varied in size from a large pea to a walnut.

Right lung showed hypostatic congestion. Left lung showed massive collapse. Liver fatty. No macroscopic abnormality detected in other organs.

The cause of death was pulmonary collapse. The jejunal diverticula were an accidental finding. The diverticula were all situated at the mesenteric border, separating the leaves of the mesentery, and their orifices, which varied according to their size, were large enough to permit easy emptying of their contents. No muscle tissue could be detected in the walls of the sacs sectioned. An atrophied mucosa covered by fibrous tissue constituted the wall.

This case is reported because of its comparative rarity. To the writer's knowledge, no case has so far been reported in the medical press in India. This is the first case he has encountered amongst the pathological autopsies performed in the King Edward Medical College, Lahore, during the last 15 years. The college museum is about 60 years old and does not possess any specimen of multiple diverticula of the jejuno-ileum.

Ian Fraser (1933), writing on diverticula of the jejuno-ileum, reports coming across only two cases on going through 5,000 case records in the Royal Victoria Hospital, Belfast.

He quotes Sheppe as having collected only 30 cases from the literature of 80 years until 1923, Reinhardt finding three cases only out of 5,000 autopsies and Henri Goddard 16 out of 13,069.

The incidence of this condition is roughly stated to be as one per thousand. Results of exploratory laparotomies since 1914 and to radiography since 1920 are also reported to emphasize the rarity of this condition. This abnormality is said to occur in elderly people. Ian Fraser quotes cases, finding the average age for men in his series as 66 and for women 60. The preponderating incidence is reported to be in the male sex. Twenty-nine males to 11 females were found in a series of 40 cases and the enlargement of the prostate was a frequent finding in many of the males. Diverticula of the colon, Meckel's, and duodenum are fairly common and figure among the exhibits of most pathological museums in India; not so the jejuno-ileal diverticula, particularly the multiple variety incident in the upper part of the jejunum as found in the case under report.

The museum of the Calcutta Medical College, about the richest in India in the number of its exhibits, has five specimens of jejunal diverticula, of which only one shows the multiple variety with three large diverticula in the upper part of the jejunum. This specimen was collected in 1901. The other four specimens show just one diverticulum each and two of these represent the commoner type occurring at the duodeno-jejunal junction. It has three specimens showing one diverticulum each in the ileum.

The museum of the King George's Medical College, Lucknow, possesses two specimens of diverticula of the small intestine, of which only one is of the multiple variety and similar to that of the case under report.

The museum of the Madras Medical College possesses three specimens of diverticulosis of the

small intestine, of which but one is of the multiple variety.

In the Bombay Pathological Museum the writer did not come across any specimen of multiple diverticulosis of the jejunum analogous to the one described in this paper.

On the basis of age-incidence and anatomical position, multiple diverticula of the jejuno-ileum are supposed to follow the sclerosis of vasa recta arising from the superior mesenteric artery.

Holvestine (quoted by Ian Fraser) also considered rise in intra-abdominal pressure associated with conditions of strain, as in cases with enlarged prostate, a probable ætiological factor.

The case under discussion had at least the factors of age and prostatic hypertrophy qualifying him for exhibiting jejunal diverticulosis.

I am very grateful to Dr. Hamid and Dr. Tirumurtie, Professors of Pathology, respectively at Lucknow and Madras, for the detailed information they have furnished me regarding the specimens in their museums.

A CASE OF BREAST CANCER IN A MALE

By A. C. DEY, L.M.F. (Cal.)

Senior Resident Medical Officer, Astanga Ayurveda Hospital, Calcutta

M. L. S., Hindu, male, aged 50 years, a resident of the Dacca district, was admitted to the

Astanga Ayurveda Hospital on 25th May, 1936, for the treatment of a large circular fungating mass on the right mamma.

Previous history.—The patient said that about two years ago he noticed a small tubercle-like growth on the right nipple. Gradually it went on increasing

in size and in the course of a few months, he began to feel uncomfortable while wearing underwear and shirts. He consulted a local medical practitioner who removed the growth. A few months after the operation, he noticed a bigger mass than the first just beneath the incised area and was again operated upon. The second operation gave him no relief and instead a raw surface was left. He again consulted a medical practitioner who incised and scraped the part and stitched it up. But the stitches gave way after a few days leaving a raw area about four to five inches in diameter and a gradually increasing hard mass. The patient did not give any history of any constitutional disturbance in the beginning of his illness but said that after the third operation which was about a year before his admission, he began to get moderate rise of temperature and other constitutional disturbances such as anorexia, constipation, gradual loss of weight and strength, sleeplessness due to local pain, and a disturbed state of mind. From the raw area there was purulent discharge and the surface bled on slight touch. As the patient was a business man he continued his normal duties as far as practicable with his clothing on, which caused occasional friction and bleeding from the wound. The patient gave no history of wearing any tight clothing and there was no abrasion or scratch over the site of the growth before it appeared.

Condition on admission.—The patient looked very ill and was extremely anxious to have the tumour removed as he was in great distress. Pulse rate 115/26 per minute. Axillary temperature—101°F. Tongue—coated and dry. Lungs—no adventitious sounds present. Heart—no adventitious sounds at the apex, aortic or tricuspid areas. The pulmonary area presented a systolic bruit (hæmic). The liver and spleen—not palpable. Axillary and cervical lymph glands were not palpable.

There was a cauliflower-like growth in connection with the right mamma with profuse foul-smelling discharge and slough over the surface. The tumour bled on slight interference. The root was four inches in diameter. The breadth of the tumour was nine inches and the circumference 23 inches. The blood picture showed typical secondary anæmia with a hæmoglobin value of 32 per cent (Sahli) and a total red cell count of 1,530,000 per c.mm. and a moderate degree of leucocytosis. The hæmoglobin and total red cells increased to some extent with a course of iron and arsenic injections in combination with liver preparations but this increase was transitory due to hæmorrhage off and on.

Treatment was aimed at improving the blood condition (a course of whole blood was given but no transfusion was possible for want of a donor), and relieving other constitutional troubles. Local application of styptic and antiseptic lotions were used and a few exposures to diathermy were given. No operative procedure was undertaken for fear of hæmorrhage and the poor condition of the patient. Sectional examination revealed it to be a spheroidal-celled cancer with much fibrous tissue and scanty epithelial cells and the patient died on 11th November, 1936.

Special points to note in this case are:—

(1) Rarity in males, (2) huge size, (3) absence of metastases.

I wish to thank Dr. D. P. Ghosh, B.A., M.B., the visiting surgeon, for kindly allowing me to publish the notes of this case.

[Note.—If, as the writer seems to think, the anæmia was due to blood loss, it was unnecessary to consider blood transfusion, however many donors had been available. Large doses of iron would almost certainly have doubled the hæmoglobin percentage, after which the patient might have been fit to undergo an operation. Whether or not this would have been worth while undertaking is, however, another matter.—Editor, I. M. G.]

GASTRIC CANCER IN A GIRL OF 19

By ABINAS CHANDRA DE, L.M.P.

Assistant Medical Officer, Rajgarhali T. E., Makum Junction P. O. (Assam)

A GIRL, about 19 years of age and mother of one child about three years old, was admitted into the hospital on 18th April, 1937, with complaint of a constant pain and flatulent distension of the abdomen, and a feeling of distress and increased pain about the epigastrium after taking food. This was partly relieved by vomiting four to six hours after meals. These and other minor dyspeptic troubles had continued for a little over a month previous to her admission into the hospital. She also gave a history of amenorrhœa for four months.

Physical examination.—Abdomen highly distended with gas. Spleen and liver enlarged. Stomach could not be outlined owing to excessive flatulence. Temperature 97°F., pulse 90, respiration 28 per minute, heart slightly dilated, with hæmic murmur over precordium. Lungs normal. Hæmoglobin 30 per cent (Tallqvist). Urine normal. No signs of pregnancy and no abnormal tumour could be felt in the epigastrium or any other situation. Vomit contained undigested rice and other food particles. Cachexia was marked.

She lived for 28 days after admission during which time the following points were observed:—

From the day after admission she started to get a rise in temperature which continued irregularly till her death on 15th May. Her flatulence could not be relieved up to the last in spite of very careful and judicious dietary and carminatives. It was only three days before death that a hard and nodular growth could be felt in the epigastric region; it was tender on manipulation and slightly movable. During the latter part of her stay in hospital she used to vomit at long intervals and brought up typical coffee-ground liquid in abundance and her pain also increased severely for which free administration of opiates became necessary.

Post-mortem examination.—On opening the abdomen the stomach was found to be highly dilated and its great curvature displaced downwards almost into the pelvis. It contained ten ounces of viscous fluid. The gastric mucosa was thickened and injected; no ulcer found. A tumour was found in the pyloric end attached to its lesser curvature. On dissecting out the tumour it appeared nearly round and measured six inches in circumference. It was hard and irregular on the surface with papillomatous projections. No sign of ulceration was noticed on its surface. The pyloric orifice was highly stenosed. The duodenal end of the pylorus was taken out and on section diffuse spots of induration were visible on its mucous surface. Lymphatic glands along the lesser curvature were enlarged and indurated and some of the neighbouring mesenteric glands were also found similarly involved.

Pathological report.—Sections from the tumour were sent to the pathologist, Berry White Medical School, Dibrugarh, for examination and report who stated 'The histological picture is suggestive of adeno-carcinoma'.

The extreme rarity of gastric cancer at such an early age and its peculiarly short duration (only a little over two months from the first symptom to death of the patient) are of interest.

My thanks are due to Dr. H. L. Slaughter for his permission to publish this case note, and also to Dr. R. M. Deb for the histological report.

Indian Medical Gazette

APRIL

HYDATID DISEASE

A FEW years ago attention was drawn to the apparent frequency of *Cysticercus cellulosæ* in man in India by the reporting of this infection in a relatively large number of British soldiers, who appeared to have acquired it while stationed here, but from the literature the impression is gained that *Tænia solium* in human beings, and the larval stage in pigs and men, are rare. We venture to express the opinion that such an impression is false and is engendered by lack of adequate information on the incidence of this condition among the indigenous population.

Much the same state of affairs exists regarding hydatid disease and about five years ago a short paper appeared in our columns in which indirect evidence was adduced that hydatids are really much commoner in India than published records would lead one to suppose.

Until recently there was no further support for this conclusion because only three or four reports of single cases had appeared in the literature in the intervening period. In our issue of February last, however, there is a paper of great interest and importance regarding hydatid disease in this country. This paper gives records of twenty-seven cases proved by operation to be hydatids and thirteen more diagnosed clinically. That is, a total of forty persons with hydatid disease attended one small district hospital in the course of about six years, and it should be noted that these figures probably only represent a fraction of the actual cases that really exist in the area, because it is probable that many have not presented themselves at the hospital, either on account of the prejudice against such institutions that unfortunately is still common, or on account of distance making attendance difficult or impossible. The population from which this hospital draws its clientele is approximately 200,000, and as far as evidence is available the hydatid-infected members of the community come from all over the district and all castes appear to be equally represented. It therefore cannot be accounted for by a small heavily-infected focus that might be explained by special local conditions.

The medical officer who furnished this report carried his investigations further and found that over fifty-two per cent of the stray dogs he examined harboured the adult *Echinococcus granulosus* and that over 89 per cent of the cattle showed larval infection; sheep and goats

are apparently not commonly infected. With such a high incidence of animal infection it is not surprising that the disease is common in human beings also, more especially as the water supply is distinctly primitive and the opportunities of its contamination by dogs innumerable.

This record is in itself perhaps not very startling when the total population of India is taken into account, but there is no reason for assuming that this small district is in any way different from hundreds of others, so that there is little doubt that the incidence of hydatid disease is equally heavy in many other parts of the country and that it must be producing high mortality and morbidity rates that at present are not being recorded. Unfortunately, the onset of the disease is insidious, it usually takes years to develop, it exerts a continual and steady drain on the health of the population and it never attracts attention by an epidemic outburst, so that its serious character is not appreciated by the general public, and no demand is made that such an important menace to health should be prevented.

The life history of this parasite has been thoroughly worked out and it is briefly this. Dogs, and to a lesser extent wild carnivora such as jackals and wolves, eat the flesh of cattle and sheep that contains the cystic or larval stage of the worm known as hydatid cysts. They develop in the intestine of these animals into adult worms and the eggs are passed in the faeces. When the water supply is drawn from surface tanks it is practically without exception polluted with the faeces of all domestic animals, including dogs, so that the high rate of animal incidence is maintained, and man, who drinks the water from these tanks also, frequently becomes the victim of hydatid disease.

It is clear that infection with this parasite can easily be prevented by approaching the problem from the single direction of dealing with dogs. The number of unwanted dogs in every village and town in India is too well known to need enlarging upon and the importance of their destruction has long been recognized as a means of reducing rabies, and to this should be added the danger of their transmitting hydatid disease, as further reason for their extermination. Properly-cared-for dogs whose feeding is controlled need not be got rid of because if they are prevented from eating contaminated meat they are no danger to man in this connection.

Such a step in the direction of disease prevention in the villages will need education of the individual and this appeals to us as one of the aspects of public health improvement that could be very effectively dealt with by the rural health units that are becoming gradually established in the country districts.

Special Article

CONDITIONED REFLEXES*

By S. L. BHATIA, M.C., M.A., M.D. (Cantab.), F.R.C.P. (Lond.), F.R.S.E.

LIEUTENANT-COLONEL, I.M.S.

Dean and Professor of Physiology, Grant Medical College, Bombay

I.

THE main facts about the conditioned reflexes are no doubt known to you all. They are well established and may be briefly described. Pavlov introduced a new method for investigating the normal functions of the central nervous system and especially of the higher centres. He divides all reflexes into 'unconditioned' and 'conditioned'. The 'unconditioned reflexes' are inborn and transmitted by heredity. The conditions in which an animal lives do not influence their formation. All the spinal and bulbar reflexes including the visceral, somatic, protective, postural, feeding and sexual reflexes belong to this group. They are probably the basis of 'instinct'. The 'conditioned reflexes' on the other hand are acquired during the life of the individual. Consequently they are individual in their distribution and unlike unconditioned reflexes do not belong equally to all the members of the species. The conditions in which an animal lives determine their formation. Adaptation to environment depends on the power of the individual to acquire new conditioned reflexes—on his power to learn, unlearn, and learn again according to the variations in the conditions in which he lives. It is not known to what extent these reflexes are hereditary. They are characteristic of the higher animals, in whom the brain possesses a vast amount of 'associations' between different centres, and the faculty of discrimination and judgment. They originate in association with well-established unconditioned reflexes, which form the substratum. Quite a number of such reflexes may be developed around a simple inborn reflex. 'The higher the animal's nervous system, the greater the number and complexity of the conditioned activities it presents' (H. Hartridge.)

You all know the classical example of a conditioned reflex. When food or acid is placed in the mouth of a dog, a reflex secretion of saliva is produced, which can be collected from an artificial fistula and measured. This is an unconditioned reflex with its centre in the medulla, and can be elicited in a decerebrate animal. Now if a second indifferent stimulus such as a sound is applied when the animal is being fed or just before, and this act is repeated

a number of times, the sound becomes an adequate stimulus for the production of saliva, even without food or acid in the mouth. This is a conditioned reflex. At first the reflex is diffuse but by further repetition and training it becomes localized, so that a particular note only will evoke a response. In the dog a differentiation between a note of 800 and one of 812 vibrations can be established. This differentiation is due to a process of internal inhibition.

For these experiments the salivary gland is used most often because the response (secretion of saliva) can be determined quantitatively, but visual, tactile and all types of sensory end-organs and many varieties of stimuli can be used to establish these reflexes. Apart from the salivary secretion, the other varieties of responses used are the contractions of skeletal muscles, reactions of pupil, changes in the heart rate, gastro-intestinal movements and secretions, respiration, and reactions of the vasomotor system.

The conditioned reflexes are of two varieties, namely *positive or excitatory*, and *negative or inhibitory*. The conditions necessary for the establishment of the positive reflexes are that the animal should be in good health, the conditioned stimulus should begin to operate before the unconditioned stimulus is applied, and slightly overlap the latter. An alert mental condition of the animal is necessary. The cerebral cortex must be protected from other conflicting modes of stimulation. For this reason, the experiments are carried out in a dark, sound-proof room away from the observer, who watches the animal through a window. Almost any stimulus can become suitable if properly applied. It is necessary that it should be followed or 'reinforced' by the unconditioned stimulus. 'Trace' conditioned reflexes, either 'short' or 'long', are established when a definite interval elapses between the conditioned and unconditioned stimuli. Even 'duration of time' may become a conditioned stimulus.

New conditioned reflexes can be established by 'linking' the action of a new stimulus with a conditioned reflex already established. These are known as 'secondary' conditioned reflexes. Tertiary, quaternary, and other reflexes without end can be established in man; but in the dog tertiary reflexes are the limit. This phenomenon of 'linking' indicates the manner by which the most complicated associations are developed in the cortex by building one reflex upon another. This function is acquired by each individual, the process being one of *signalization*, by which a signal or an unconditioned stimulus evokes the same response as the stimulus with which it has been primarily associated.

The conditioned reflexes obey certain physiological laws, namely summation, irradiation, specificity, discrimination, reinforcement and linking.

The negative conditioned reflexes cause inhibition instead of excitation. They are due to

* Paper read at the Indian Science Congress, Hyderabad, Deccan, January 1937.

the faculty possessed by the cortex of discriminating between the stimuli, so that unsuitable responses do not occur. These reflexes are of various sorts, but probably the ultimate mechanism of all is the same. This inhibition is an active process and it may be external or internal. External inhibition is due to the presence of an extraneous stimulus and may be temporary or permanent. It appears to depend on the impulse rather than on the acquired properties of the cortex. Internal inhibition is dependent on the inhibitory discharges from the cortical cells. It occurs when the conditioned stimulus is repeated without the accompaniment of the unconditioned stimulus. Its examples are the phenomena of inhibition by *extinction*, conditioned inhibition, inhibition by retardation and differential inhibition. There is again the phenomenon of *disinhibition*, or inhibition of inhibition, by which one inhibitory process can inhibit another, so that the original excitatory reflex occurs.

The conditioned reflexes are a function of the cerebral cortex. The primary function of the nervous system, according to Pavlov, is to maintain a dynamic equilibrium between the functional units within the self-contained system of the organism and between the organism as a whole and its environment. The pre-eminent function of the lower parts of the central nervous system is to integrate the activities of the separate parts within the organism. But the most delicate adjustments between the organism and its environment are pre-eminently the function of the cerebral hemispheres. Removal of the cortex abolishes all conditioned reflexes, and prevents the formation of new ones. Localized damage produces partial loss, but the establishment of inhibitory reflexes becomes particularly difficult. The cortex is therefore an important inhibitory organ.

The *reflex arc*, according to Pavlov, is divided into three parts:—

(1) The part that begins in every natural peripheral end of the centripetal nerve and ends in the receptor cell in the central nervous system. This is known as the *analyser*. The task of this consists in decomposing the entire world of stimulating influences falling on the organism from the outside. The higher the animal, the finer is their decomposition.

(2) The part which must join the brain end of this analyser with the effector apparatus. This is known as the *connection* or *lock*.

(3) The working apparatus or the *effector* organ.

Pavlov asserts that the cerebral hemispheres consist of sensory or receptive centres, *viz*, the brain endings of the analysers. It would appear that a considerable part of the hemisphere is composed of these analysers. The occipital and temporal regions are of course the centres for eye and ear respectively. Even the so-called motor centres should be considered receptor

centres from another receptor surface which has a special relation to movement.

The peripheral apparatus, the analyser, consists of a number of so-called transformers which convert different forms of energy into nerve energy. And a conditioned reflex is an act of synthesis by the cerebral cortex, the whole of which is concerned with the reception of impulses. Irradiation and concentration are fundamental laws of higher mental activity.

II.

Conditioned reflexes thus offer us the means of objective investigation of the activity of the central nervous system. They have certain important applications in the case of man. They are probably the basis of training and education, and are related to the 'behaviour' of the individual. Formation of 'habits' depends on acquiring certain conditioned reflexes.

Man's capability to develop links in the conditioned reflexes seems to be unlimited. This greatly increases the scope of his activities. 'A signal to which the animal was previously indifferent acquires executive power; it becomes a spring of further action. It amplifies the animal's behaviour. The new connection improves with use; under disuse it disappears. It can therefore hardly be morphological. Professor McDougall is trying to see if it is heritable. Anyway the great new surface net of the brain is educable. Before it, truly, there were educable systems in the animal world, but this is so educable as to be practically a new thing in the world. In the dog it can acquire these new links even in a few repetitions, and links can be combined even to the third degree. In man it seems they can develop almost without limit' (Sir C. Sherrington). Thus the human brain is capable of being educated almost endlessly. The study of conditioned reflexes also shows the plastic adaptability of the central nervous system by means of which adjustment to external environment occurs.

Another interesting outcome of this work is that it has been found that dogs show marked individual differences in regard to the *facility* with which these reflexes are acquired. In some they are more stable than in others. Some acquire the positive or the excitatory reflexes more easily, others the negative or the inhibitory.

Thus Pavlov divides his dogs into four different groups, namely two extreme groups of markedly excitatory and inhibitory animals, and two central groups of well-balanced, equilibrated animals, but also different—one being quiet and the other exceedingly lively. These results are applied to man, who is said to possess four types of temperaments. The ancient grouping of temperaments according to Hippocrates into choleric, melancholic, sanguine and phlegmatic is essentially correct. The excitatory type is the choleric, the inhibitory is the

melancholic, the phlegmatic type is well-balanced, self-contained and quiet, while the sanguine is also well-balanced and energetic, when there is a constant stimulus but in the absence of a stimulus it becomes slothful. In an extreme case the excitatory choleric type merges into the pathological form known as neurasthenic, and the inhibitory melancholic type into the hysterical. Thus this knowledge also helps us to understand the various forms of psychoses.

In considering the functions of any organ in the body, we as physiologists think in terms of chemical reactions, production of heat, action potentials, exchange of energy, the structure and functions of individual cells. In the case of the brain also, we consider all this. In addition to this we have in conditioned reflexes an objective method of studying some of the responses to stimuli that occur in higher animals. But in studying the functions of the brain, it is impossible to divorce the mental process from the physiological. What is the relation of these two processes to each other? How does one influence the other? Have they both a common origin? Are mind and matter two different things? Pavlov says that they are not. 'We are now coming to think of the mind, the

soul and matter as all one, and with this view there will be no necessity for a choice between them'. He thinks that this dualistic theory has kept physiologists from working with the higher nervous phenomena. May it not be that in order to understand fully how the brain works, we require the joint efforts of physiologists and psychologists. It is in order to bring about this liaison that this joint session of the two sections has been held here to-day. I trust, that this liaison will endure to the mutual benefit of both physiology and psychology.

Medical News

SUMMARY OF TUBERCULOSIS NEWS FOR THE MONTH OF FEBRUARY 1938

THE report of the 10th Conference of the International Union against Tuberculosis has been recently received. The conference was held in Lisbon from 5th to 10th September, 1937, and was attended by well-known phthisiologists from various countries. The reports of Professor Lopo de Carvalho on radiological aspect of the hilum, by Dr. Sachel on primary infection in the adolescent and adult, by Dr. Hatfield and Dr. Powell on tuberculosis prophylaxis in the home, do not merely provide interesting information and define the present scientific status of the problem, but have given new ideas for scientific discussion and further research.

In accordance with the recommendation of the executive committee, the council decided to hold the next conference in Berlin in 1939. The exact dates will be settled later.

The International Union serves a valuable purpose of bringing together nations, which have a common object in prevention, study and treatment of tuberculosis. Forty-four countries are now adherent to the Union. The Union not merely manifests itself by its conferences, it is a permanent body, the activities of which include meetings of the executive committee, an annual meeting, the publication of a quarterly journal, as well as some affiliated activities. The Bulletin is the only bond that unites the members of the Union in the interval between the conferences. It keeps the readers informed about the Union's activities and also to a certain extent reflects the main trend of international phthisiology. Of the several associated activities of the Union, a commission under Dr. Bachmann (Zurich) has issued a very interesting report on the practical solution, which has been reached so far, on the conditions required to make post-sanatorial assistance as effective as possible. The report deals with sanatorium

statistics and the conclusions to be drawn from them about after-care work, and discusses the possibility of conciliating the reduced working capacity with a normal salary and gives information about the organization of the rehabilitation and post-sanatorial assistance, and mentions the various solutions that have been realized up to date.

HEALTH LEAGUES FOR VILLAGES : EDUCATING THE CHILDREN OF INDIA

THAT health leagues should be created in every village in India to fight disease and improve the standard of life was urged by Colonel A. J. H. Russell, Public Health Commissioner with the Government of India, in a talk broadcast from Delhi recently.

Dealing with the launching of a rural hygiene campaign, Colonel Russell said: The first point I would make is that no advance can be expected unless the agencies at work, whether governmental or non-official, secure the villagers' active co-operation. It is now generally recognized, indeed, that public health measures thrust on a community by compulsion can never produce permanent results.

This co-operation can only be obtained by preliminary educational work directed towards developing the villager's interest in schemes for his betterment.

Whilst the most fruitful results will probably be attained by teaching the children, the adult must not be neglected, for although the Indian villager does not readily accept new ideas, community life is not unknown to him nor is the ideal of service alien to his outlook.

Successful preliminary work of this kind will make further advance possible through the formation of village organizations whose members devote both time and service to the common good. Members of co-operative societies and non-official agencies, inspired with this purpose, may thus be induced to form health

leagues for each village or group of villages, whose objects are to develop the ideal of self-help in relation to the care and promotion of their own health.

Patient presentation of facts bearing on the advantages of personal and environmental hygiene—by means of lectures, talks, personal conferences and house-to-house visits—is the first step to be taken in order to arouse in the villager a sanitary conscience, although the great difficulty here is that we are dealing with people who to a large extent have not been conversant with sanitary principles in childhood.

ALL CLASSES ELIGIBLE

All classes of the community should be eligible for membership and every individual in the village should be encouraged to make his contribution to the approved health programme. Some will most conveniently make their contributions in the form of money, but the poorer members should be permitted to offer free labour, which has been an age-long custom in many parts of India.

Labour devoted, for example, to the cleaning of the village tank or the excavation of manure pits will be equally acceptable and by such means all sections of the community will have the satisfaction of taking an active part in the betterment of their own surroundings.

The public health officer of the area and other officials should all assist to their utmost; the health officer should, for instance, attend all meetings of the health league when public health measures are being discussed, in order to guide and advise so that waste of effort may be avoided. Once the foundations of confidence and interest are well and truly laid, the superstructure of health improvements should be easy to erect.

As the health unit's activities (a unit comprising a population of about 40,000) should all be based on standard public health methods, a permanent staff of trained workers must be provided. The cost of this staff is the contribution which can be suitably made by the governmental or local authority primarily responsible for the welfare of the population.

IMPORTANCE OF STAFF

In the first place, a trained and experienced health officer is essential, because the success or failure of the scheme depends largely on his capacity to develop the team spirit in his subordinates and in the villagers, through the health leagues.

He it is who is mainly responsible for the education work to which reference has already been made, but the other members of his staff, which should include four qualified sanitary inspectors, four trained health visitors, eight certified midwives and if possible a woman doctor, must also take a continuously active part in the same task in their respective spheres of action.

One of the first activities that might be usefully undertaken is the prevention of smallpox, which is such a common disease. If the entire population is properly vaccinated, the people can be assured that further outbreaks of smallpox will not occur for several years.

If a survey, on the other hand, reveals that malaria is a major problem, suitable methods of control including mass quininization should be put into practice at once.

In these and other ways suited to the area, the villagers will obtain concrete demonstrations of the value of the health unit scheme and will be the more willing to take part in other activities recommended by the health staff.

NEED FOR STATISTICS

The proper evaluation of all health work depends on the accuracy of vital and health statistics and the health staff must make early efforts to improve birth and death registration and the records of diseases such as smallpox, plague and cholera.

The co-operation of village headmen, school teachers, and revenue officials should be enlisted for this purpose

and, if this work is properly handled, the health officer should soon be in possession of accurate details not only of prevailing birth and death rates but of the incidence of every important disease in his area.

Uninformed opinion is often inclined to consider the collection of these records to be a waste of time and money, but the fact remains that no real estimate of progress in public health can be made without them.

'PERSUADE THE WOMEN'

I must refer to another important part of a well-planned health unit scheme, *viz.* the care of the mothers and children. This is the main function of the health visitors and midwives, although the health officer himself is also intimately concerned.

In India this work, however, can only be carried on by women, because the majority of homes are closed to men workers. Educated Indian women have so far failed to realize the vast opportunities awaiting them in this field and it is at present impossible to obtain a sufficiency of trained workers.

At convenient centres throughout the area, clinics should be provided at which the mothers can obtain skilled advice for themselves and their infants and young children. By talking to individual women and by demonstrations given during home visits, the health visitors will be able to gain the confidence of the mothers, to induce them to attend at the clinics and to put into practice the advice they are given.

The clinics should be made as attractive as possible, otherwise the attendance will decline. At quite an early stage, it should be possible to give instructions in sewing, knitting and in the feeding of weak and sick infants, and on every possible occasion carefully prepared talks on different subjects should be a part of the day's programme.

Persuade the women that polluted water, the lack of sanitation and swarms of flies are grave dangers to their children and the health campaign will be won.

200,000 DIE IN CHILD-BIRTH

A moderate estimate indicates that every year about 200,000 women die in child-birth in this country and that no less than 1½ million infants die before they reach the age of one year. These figures represent an incalculable amount of suffering, pain and loss which is largely preventable and which can only be prevented when women trained in preventive medicine become available.

I believe that by some such organization, working in close co-operation with others of the same kind, satisfactory progress can be made in respect of the public health part of a rural reconstruction campaign.

ANNUAL MALARIA CONTROL COURSE FOR LAYMEN

THIS course which is intended for non-medical residents in the tropics, home on leave or those about to take up appointments abroad (engineers, planters, etc.), will be held at the London School of Hygiene and Tropical Medicine commencing on Monday, 27th June, 1938, at 10 a.m.

(1) The course will be under Sir Malcolm Watson, Director of the Ross Institute of Tropical Hygiene.

(2) The course lasts five days, and ends on Friday, 1st July, 1938. Except on Friday, 1st July, the lectures of the malaria control course are given in the mornings only; but (in response to numerous requests from those who have attended in the past) additional afternoon lectures and demonstrations have been arranged on (a) water supplies, (b) conservancy and sewage disposal, (c) insulation against heat and cold, air conditioning for comfort in the tropics.

(3) The course is designed for planters and mining engineers, but it will be of interest to all (including missionaries) who are proceeding to the tropics. Doctors may attend, but the course is primarily for laymen.

(4) It includes instruction on mosquitoes and their habits, drainage and other measures for the prevention of malaria. It is illustrated by lantern slides, films,

demonstrations of the living insect in the various stages of its history, and a practical demonstration on Hampstead Heath.

(5) The course is free. Applications to attend the course should be sent in as early as possible, to the organizing secretary at the Ross Institute of Tropical Hygiene, Keppel Street (Gower Street), London, W.C.1.

(6) The most convenient underground railway stations serving the school are Tottenham Court Road, Goodge Street, Russell Square.

(7) Luncheon can be obtained at the school.

INDIAN MEDICAL RESEARCH

The Indian Research Fund Association will have its annual grant raised from Rs. 1½ lakhs to Rs. 4½ lakhs from next year as a result of certain proposals now under consideration of the Government of India.

The Indian Research Fund Association is a local body established in 1911 for the prosecution and assistance of research, propagation of knowledge and for experimental work generally in connection with the causation, mode of spread, and prevention of diseases primarily of a communicable nature. It has received from the Central revenues ever since its inception an annual grant-in-aid which amounted in 1931-32 to Rs. 7½ lakhs, the total contribution to the Association made by the Government of India so far being nearly a crore of rupees.

RESERVE FUND STEADILY DEPLETED

As a measure of retrenchment that grant was reduced to Rs. 1½ lakhs per annum from 1932-33 and still stands at that figure. In consequence the Association found itself compelled to draw up its research programme on a restricted basis and even then had to withdraw annually a sum of Rs. 3 to 4 lakhs from its invested funds which stood at a little over Rs. 52 lakhs (face value) in 1932-33 and which, as a result of gradual reduction and of the transference of the share of the Government of Burma, will shortly be reduced to about Rs. 31 lakhs (face value).

The reserve funds of the Association were thus in danger of steady depletion to a point where it would have been difficult for it to draw on them in emergency for maintenance of its general research activities.

Though the present increase does not restore the grant to its pre-depression figure, it is believed that this will substantially help the Association in tiding over its financial difficulties.

INDIAN RED CROSS SOCIETY

MISS NORAH HILL, A.R.M.C., organizing secretary, Indian Red Cross Society, and General Secretary, St. John Ambulance Association (Indian Council), has left the Indian Red Cross Society, on termination of contract, after nine years of service in India, at the end of February.

Coming to India as organizing secretary of the Indian Red Cross Society in 1929, she brought with her the varied experience of fifteen years' work for the Red Cross. The widespread activities of the Red Cross in India and its increasing recognition as a national health-building agency are in no small measure due to her energy and organization. Of the numerous schemes initiated by her, mention must be made of the trained-nurses' roll which proved of great value during the recent Bihar train disaster. She is responsible for the cinema section of the Indian Red Cross Society, which has to-day a large library of health films produced by the section itself and bought from other countries. She was awarded the 'Cross of Merit' by the Japanese Red Cross when she visited Japan as leader of the Society's delegation to the International Red Cross Conference in 1934. In the same year she became an Officer (Sister) of the Order of St. John for her untiring work as General Secretary of the St. John Ambulance Association. In 1935, Miss Hill was awarded the King's Silver Jubilee Medal and she received the Kaiser-i-Hind Medal, First Class, in 1937. In May she added the

Coronation Medal to her list of international decorations.

She is succeeded by K. B. Dr. Abdul Hamid, D.P.H. Dr. Hamid was one of the assistant directors of public health in the United Provinces, where he also acted as honorary secretary of the U. P. branch of the Indian Red Cross Society for a number of years.

INDIAN MEDICAL COUNCIL

MAJOR-GENERAL H. C. BUCKLEY, K.H.P., I.M.S., is nominated as a member of the Medical Council of India from Bombay, *vice* Lieutenant-Colonel S. L. Bhatia, I.M.S., resigned.

Colonel D. H. Rai, I.M.S., is nominated as a member of the Medical Council of India from the C. P. and Berar, *vice* Colonel K. V. Kukday, C.I.E., I.M.S. (retired), resigned.

Colonel H. Stott, O.B.E., I.M.S., is nominated as a member of the Medical Council of India from Bihar, *vice* Major-General P. S. Mills, I.M.S., resigned.

Lieutenant-Colonel P. S. Bharucha, D.S.O., O.B.E., I.M.S., has been duly elected as a member of the Medical Council of India, *vice* Khan Bahadur Dr. K. A. R. Rahman, O.B.E., resigned.

BOMBAY MEDICAL COUNCIL

NOTICE

The Bombay Medical Council will welcome suggestions from registered medical practitioners, medical associations, etc., regarding the revision of the Code of Medical Ethics. The suggestions should be sent to the Registrar, Bombay Medical Council, at 19, New Marine Lines, Bombay.

THE MADURA MEDICAL ASSOCIATION

Tenth Annual Report

The number of members on the rolls is 78 and shows an increase of 19 over the figures for the last year.

There were eleven ordinary clinical meetings of the association of which one was a joint meeting of The Madura and Ramnad Medical Association held at Madura, one a similar two-districts' meeting held at Ramnad and another at Madura of the Madura, Ramnad and Tinnevely Medical Associations.

SILIGURI MEDICAL ASSOCIATION

The medical profession in Siliguri has recently united into an association, with Dr. J. N. Sengupta as president and Drs. J. C. Bhattacharjee and M. N. Biswas as joint secretaries. The membership is open to all allopathic medical practitioners. The secretaries appeal through this journal to all medical men of Darjeeling Terai to join the association.

THE PARKES MEMORIAL PRIZE, 1937

MAJOR J. BIGGAM, M.C., R.A.M.C., has been awarded the Parkes Memorial Prize for his very valuable investigations into the lighting of barracks and other military institutions coupled with important work he has carried out in regard to the effect on vision of the wearing of the service respirator and the designing of a suitable spectacle frame for wearing with the respirator by men with impaired vision.

The Parkes Memorial Prize is awarded annually to the officer who is considered, by the Committee, to have done most to promote the advancement of Naval or Military Hygiene by professional work of outstanding merit, and is open to Medical Officers of the Royal Navy, Army, and Indian Army with the exception of the Professors and Assistant Professors of the Royal Naval Medical College, Greenwich, and of the Royal Army Medical College, London, during their term of office.

Epidemic of Paratyphoid B Fever

By W. M. FRAZER, M.D., M.Sc., D.P.H.
B. T. J. GLOVER, M.D., D.P.H.

and

V. GLASS, M.B., B.S., M.R.C.S., L.R.C.P.
(From the *British Medical Journal*, Vol. II,
21st August, 1937, p. 369)

ON 4th January, 1937, was notified the first of a series of cases of paratyphoid B fever in an outbreak which aggregated 132 primary cases before it was ended, of which 107 cases were in Liverpool, sixteen in the adjoining town of Bootle, seven in the rural districts surrounding Liverpool and Bootle, and two in North Wales. The quick succession of notifications—there were seventeen in the first week and thirty-three in the second week—and the widespread distribution in the city led to an immediate examination of samples of water from both Wymwy and Rivington supplies. The results were entirely negative, as indeed had been the results of the frequent routine bacteriological water examinations during the previous two months.

As the cases were notified they were charted on a graph according to their date of onset and entered on a map in accordance with the site of residence of the patients. Two features of the outbreak were quickly discerned—namely, that the majority of the cases had their date of onset at the end of December and beginning of January, and that the south end of Liverpool was escaping completely. One case notified from the south of Liverpool which appeared to be an exception proved to be one of pneumonia.

The history given by the majority of the patients showed that they obtained their milk and/or bread and/or butter, and sometimes other foodstuffs, from the same firm, hereinafter called firm A. Inquiries revealed that firm A traded through many retail shops over an area corresponding with that covered by the outbreak, and that the south end of Liverpool was supplied by an independent branch of the same firm, obtaining its food supplies from different sources. Further inquiry revealed that although some of the patients had eaten butter made by firm A, most of the butter they had purchased was of Empire or foreign origin, and had been delivered to each retail shop in the kegs in which it had been imported, there to be opened and sold in quantities to meet customers' requirements. Attention was therefore concentrated on milk and bread.

Firm A prepares pasteurized and sterilized milk, and sells approximately 8,500 gallons of the former and 1,000 gallons of the latter daily, approximately one-fifth of the milk consumed daily in Liverpool and Bootle. Out of 123 patients from whom a food history was obtained seventy-five consumed milk from this source. The pasteurizing plant is one of the latest design, and is under the regular supervision of the staff of the Health Department because this firm is one approved for the supply of milk to school children under the Milk Marketing Board's scheme. The processing and bottling arrangements are such that the milk is not touched by hand subsequent to pasteurization. It appeared, therefore, to be unlikely that the outbreak was attributable to this particular milk supply. Confirmatory support for this view was, first, that the children affected were not those who were attending the schools supplied by firm A except in a few instances, and, secondly, that the outbreak ought to have been a much greater one if it had been due to the infection of milk which was so high a proportion of the total milk consumed in the city. For these reasons attention was concentrated on the bread baked by this firm. Perhaps it is needless to add that in spite of this conclusion exhaustive inquiries were made into the recent health

of the dairy employees, and that steps of a general nature were taken, such as additional care of the hands of the staff and so on.

SOURCE OF THE INFECTION

The bakery is a very large one and is exceedingly well conducted. Out of 123 patients from whom a food history was obtained seventy-six (62 per cent) regularly consumed bread from this source. The output is approximately a quarter of a million loaves a week. As this output is but small fraction of the total number of loaves produced in Liverpool, the very high proportion of patients who ate this bread is significant. Both separated milk and water are used in baking, and although it was thought to be unlikely that anything added to the loaf before baking was the cause of the epidemic, inquiries were made into the sources of both. The water was city water stored in a tank. An examination revealed nothing of significance. The separated milk was efficiently pasteurized before use and was consequently above suspicion.

Observations were made during the night while the staff were carrying out their various duties, and it was noted that twenty employees were engaged in handling loaves after they had cooled, or were touching trays, etc., with which cold loaves would subsequently be brought into contact. It was decided to examine the blood of each of these twenty employees. The blood of five of them revealed the presence of agglutinins. Two had been inoculated with T. A. B. in the Army and in the Naval Reserve respectively, and their blood revealed the agglutinins usually found after inoculation. The blood of two others was positive to *Bact. typhosum* (H) 1 in 20. Lastly a male employee (G. E. T., aged 20), who had not been inoculated and who gave no history of illness like typhoid, either recent or remote, yielded a blood which gave a positive agglutination 1 in 20 to *Bact. paratyphosum* B (H), but was negative 1 in 20 to *Bact. typhosum* (H) and (O), and *Bact. paratyphosum* B (O), *Bact. paratyphosum* A (H), and the *Salmonella* group. This man was admitted to hospital under observation on 9th February. He proved to be a carrier of *Bact. paratyphosum* B, the organism being recovered from both the faeces and the urine on several occasions.

The patient was discharged from hospital on 27th March.

This carrier had been employed by the firm for two and a half years, for eighteen months of which time he had been handling bread after baking. Except for four days' absence with tonsillitis two years ago there was no illness which prevented him from working. He had had measles when a child, and the only other illness he could remember was an operation on his elbow in May 1933. Inquiries at the hospital where the operation was performed revealed that he was admitted for the investigation of a bone condition which was puzzling, looking neither like malignant disease nor ordinary osteomyelitis. The operation revealed a chronic osteitis of unknown origin accompanied by pus in which no organisms were found. In the opinion of the surgeon the condition was not incompatible with the belief that the abscess was of typhoid or paratyphoid origin.

The carrier had lived all his life with his father and mother. He is the eldest of six children, of whom the youngest is three years old. No member of the family gives any history of having suffered from typhoid fever or any typhoid-like illness.

From a perusal of a chart showing the daily notification of 123 cases in Liverpool and Bootle in which diagnosis was subsequently verified and the dates of onset of the 132 cases which occurred altogether it appears that the average incubation period of paratyphoid fever is twelve days.

It will be observed that there were no cases with a date of infection subsequent to the admission of the carrier to hospital. At the same time it is noteworthy that the epidemic was waning for a month before his admission. There were 118 cases infected prior to 8th January, and only fourteen between the date and 9th February, when the carrier was admitted to hospital.

This downward trend of the cases after 8th January may be accounted for partly by the increased precautions which were taken by the bakery staff in washing their hands after visiting the lavatory. It was on 12th January that special instructions were given to the staffs of both the dairy and the bakery in regard to this matter. If this carrier was in fact the cause of this outbreak, contaminating the surface of loaves with infection on his hands, it appears to be necessary to assume that the degree of contamination diminished with improvements in personal cleanliness; it may also be necessary to assume that the excretion of organisms in the urine and faeces was intermittent and variable in amount, an assumption not unreasonable in view of the intermittency of excretion during his sojourn in hospital. Unfortunately no attempt was made to estimate the number of the organisms he was excreting. There is a record, however, that a faecal specimen on 11th February yielded no organisms on direct plating, but that they were found after enrichment. The number of organisms in this specimen must therefore have been small.

Another feature is that 111 cases had been infected (assuming an incubation period of twelve days) before the first notification was received (4th January), leaving only twenty-one cases to be infected subsequently. The infection had reached the great majority of the patients before its existence was suspected.

The even distribution between males and females, not only in the totals but also at different ages, suggests infected food which is consumed by all, irrespective of age and sex. Bread as the infected food is not incompatible with this. Of the three children under one year who were regarded as cases, two were doubtful. The one in which the diagnosis was confirmed by finding the causal organism was a patient whose parents had given it crusts to chew from bread derived from firm A.

VALUE OF FAECAL CULTURES IN DIAGNOSIS

Out of 124 cases in respect of which there was information on this point, 83 per cent of the faecal specimens submitted for examination during the first week of illness were positive. The corresponding figures for the second, third, and fourth weeks of illness were that 94.2 per cent, 92 per cent, and 87.5 per cent respectively of patients had positive stools. In the case of patients in their fifth week of illness all the faecal specimens were positive. The corresponding figures for the sixth and seventh weeks were 75 per cent and 77.7 per cent respectively. The isolation of the causal organism from the stools is of great value in diagnosis even so early in the illness as the first week, and even so late as the seventh week there is a good chance of isolating the *Bact. paratyphosum* B from the first specimen of faeces submitted. Another interesting feature to which attention is called in the paper alluded to is the rate of disappearance of *Bact. paratyphosum* B from the faeces. Fifty per cent of the patients presented positive faeces in the seventh week of illness and 20 per cent were still excreting the organism in the ninth week.

An attempt was made to determine the survival of *Bact. paratyphosum* B on bread crusts. Three experiments were done with the strain isolated from the carrier. A slice half a centimetre thick was cut off the end of a fresh paper-wrapped loaf. This was cut into small rectangular pieces $1/2 \times 1$ cm., which were placed in dry sterile Petri dishes with the crust uppermost. Each crust surface was smeared with a loopful of a saline suspension containing a known number of organisms from an agar culture. The fluid disappeared into the substance of the crust remarkably quickly. The Petri dishes containing the inoculated crusts well separated from one another were stored in a dark cupboard at room temperature. At various intervals after inoculation a piece was removed from the dish and dropped into a tube of tetrathionate broth, any growth subsequently being fully identified serologically. With an inoculum of four million organisms *Bact. paratyphosum* B was recovered from the crust on the seventeenth day but not on the twenty-second or twenty-third day. When only 120 organisms were employed recovery was possible on the sixth day but not on the

seventh or twelfth day. In another experiment with six million organisms from a broth culture the crusts still yielded cultures on the thirty-third day, by which time the material under examination was exhausted. It was not possible to be satisfied that any actual multiplication of the organisms occurred in the crust. It is evident that they can remain alive for a considerable time.

Tests to determine the similarity of organisms from patients in the epidemic were undertaken. M. Kristensen and K. Bojlén (1929) have proposed to differentiate five groups of *Bact. paratyphosum* B according to the rate of fermentation of rhamnose, the fermentation of inositol, and behaviour in the Bitter test (1926), which is also dependent on rhamnose fermentation. These tests were made on ninety-five strains from forty-eight cases (including the carrier). All strains fell into the same group, Kristensen and Bojlén group R₁, the features of which are that inositol is readily fermented, rhamnose slowly, and the Bitter test is negative. Eight other strains from four cases not associated with the epidemic fell into the same group.

COURSE OF THE ILLNESS

Eighty-seven cases were treated in the Fazakerley Fever Hospital, and the following observations are from notes supplied by Dr. A. E. Hodgson, the medical superintendent. With a few exceptions the course of illness was uneventful and free from severe symptoms. Forty-one patients (47 per cent) exhibited a rash and two had intestinal haemorrhage. There was no example of perforation of the intestine. It was noteworthy that in children the onset was abrupt, with abdominal symptoms simulating an 'acute abdomen'. In three cases the carrier state persisted for a long time. In one case (J. P., female, aged 57 years) the date of onset was 26th December, 1936, and organisms were isolated from the faeces so late as 19th June, 1937. This patient was still in hospital on 21st June. The second case (H. W., female, aged 38 years), with date of onset 3rd January, 1937, was a carrier until 26th May. The third case (H. N., female, aged 42 years), with date of onset 9th January, developed cholecystitis. The gall-bladder was drained and *Bact. paratyphosum* B was isolated (5th June) from the pus.

The part played in diagnosis by bacteriological examination was a prominent one. Out of the 123 cases occurring in Liverpool and Bootle the causal organism was recovered from 111 patients, these specimens being examined in the city laboratory in 109 instances. Of the other twelve cases the diagnosis was confirmed by serological examination in nine instances. In three cases only was the diagnosis made on clinical grounds alone.

There were eleven deaths among the 123 cases in Liverpool and Bootle, a fatality rate of 9 per cent.

SUMMARY

1. An outbreak of paratyphoid B fever occurred in Liverpool and Bootle at the end of 1936 and beginning of 1937, with 123 cases and eleven deaths. An additional nine cases in rural districts were also considered to be connected with this outbreak.

2. The circumstances of the rise and decline of the epidemic were not incompatible with the belief that it was due to the infection of loaves of bread handled by a carrier of *Bact. paratyphosum* B who was discovered in a bakery from which was derived the bread consumed by 62 per cent of the patients.

3. The isolation of the causal organism from the stools of patients proved to be a great aid to diagnosis so early in the illness as the first week. Even as late as the seventh week there is a good chance of isolating the organism.

4. Fifty per cent of the patients presented positive stools in the seventh week of illness, and 20 per cent were still excreting the organism in the ninth week.

5. Ninety-five strains of *Bact. paratyphosum* B isolated from forty-eight patients all fell within Kristensen and Bojlén's group R₁.

6. The survival of *Bact. paratyphosum* B on bread crusts was established. A heavy inoculum (6 million organisms) survived at least thirty-three days, an inoculum of 4 million organisms survived seventeen days, and a light dosage of 120 organisms was recovered on the sixth day.

7. With few exceptions patients made uneventful recoveries. Forty-seven per cent exhibited a rash. In children the onset was abrupt with abdominal symptoms simulating an 'acute abdomen'. Three cases, all adult females, persisted as carriers for five months or more.

Theophylline-Ethylenediamine in Cheyne-Stokes Respiration

By O. A. S. MARAIS, M.B. (Edin.)
and

J. McMICHAEL, M.D., M.R.C.P. (Edin.)

(Abstracted from the *Lancet*, Vol. II, 21st August, 1937, p. 437)

THEOPHYLLINE-ETHYLENEDIAMINE is a combination of one molecule of theophylline with ethylenediamine.

CH_2NH_2 Theophylline
Ethylenediamine

It was first introduced by Grüter (1910) as the result of a search for a water-soluble theophylline preparation for injection. Theophylline itself is very insoluble, and even the double salt of theophylline with sodium acetate is only soluble in 25 parts of water. Theophylline-ethylenediamine however is quite soluble and easily forms a 40 per cent solution (Grüter, 1936). The ethylenediamine compound was used at first because it was non-toxic, but it was soon found that the compound had pharmacological properties not found in other forms of theophylline.

Theophylline-ethylenediamine is suitably supplied in ampoules and tablets under the trade name of Euphyllin, and it is this preparation which we have used throughout this investigation.

ACTION IN CHEYNE-STOKES RESPIRATION

It is now ten years since Vogl (1927) described the use of euphyllin as a means of abolishing Cheyne-Stokes breathing and the accompanying subjective discomfort. It is surprising, therefore, to find that, apart from a paper by Smith and others (1935) describing its influence on paroxysmal dyspnoea, little mention has been made in English of this effect of the drug. Furthermore, its mode of action in Cheyne-Stokes breathing is still in some doubt, and the elucidation of this problem is our main object. Vogl (1932), summarizing five years' experience with euphyllin in Cheyne-Stokes breathing, states that it never fails to restore the respiration to a normal type. The action is most pronounced in cases of cardiac insufficiency, but is sometimes transient, especially when the periodic respiration results from head injuries or intracranial hæmorrhage.

The following cases will illustrate the action of theophylline-ethylenediamine. In our description the terms 'Cheyne-Stokes' breathing and 'periodic' breathing may be regarded as synonymous, although we use the latter term particularly to include regular periodic waxing and waning of respiration without the true apnoeic pauses emphasized in the original description of Cheyne and Stokes.

CASE 1. *Syphilitic aortitis and atheroma*.—A retired ship's fireman, aged 68, complaining of periodic breathlessness, and giving a history of precordial pain a month previously. There was no œdema or general venous congestion, but a good deal of bronchitis and pulmonary congestion. The heart was hypertrophied and a double aortic murmur was audible. The Wassermann reaction was strongly positive, and radiography revealed diffuse dilatation of the aortic arch with calcification. Electrocardiograms showed evidence of recent coronary

thrombosis. Cheyne-Stokes breathing was pronounced, but became less obvious after rest in bed for a few weeks when the bronchitis and pulmonary congestion had subsided.

On 31st May, 1937, a single intravenous injection of 0.36 grammes euphyllin abolished completely the Cheyne-Stokes respiration during the course of a slow injection. On subsequent occasions the injection of theobromine sodium acetate (0.6 g.) and of theophylline sodium acetate (0.6 g.) intravenously failed to abolish the periodic respiration. When the latter injection was followed by 0.1 g. ethylenediamine intravenously the Cheyne-Stokes respiration disappeared. On 18th June the administration of 0.5 g. euphyllin by mouth abolished periodic breathing in about ten minutes.

In this patient the effect of euphyllin was maintained over many hours and breathing was often found to be normal in type up to 16 hours after a single dose of 0.48 g. Oral administration was also quite successful.

CASE 2. *Hypertensive heart failure*.—An engineman, aged 53, complaining of breathlessness on exertion. The blood pressure was 170/100, and he presented the usual features of severe heart failure with congestion, i.e., œdema of the legs and back, ascites, enlargement of the liver, pulmonary congestion, and cedema. The patient failed to show any maintained improvement with a succession of therapeutic measures—including digitalis, salyrgan and other diuretics, salt-free diet, and Southey's tubes—and gradually the orthopnoea became more conspicuous and was accompanied by Cheyne-Stokes respiration. Sleep was definitely disturbed by the periodic hyperpnoea, the onset of deep breaths waking him up as he was dosing off to asleep.

On 8th June, 1937, 0.36 g. euphyllin was administered intravenously and a stethograph record showed the abolition of Cheyne-Stokes respiration as the injection proceeded. This injection was given in the afternoon and that night the patient got to sleep with ease, having previously required sedatives. On 11th June the injection of 0.16 g. ethylenediamine intravenously was sufficient to abolish the apnoeic phases, but periodic increases and decreases of respiration still persisted. The subsequent injection of 0.6 g. theophylline completed the restoration of the respiratory rhythm to normal. On 14th June theophylline 0.6 g. intravenously alone was without effect and only transient abolition of the Cheyne-Stokes breathing was achieved by 0.16 g. of the ethylenediamine given a few minutes later. On the 15th, 0.48 g. euphyllin intravenously abolished the Cheyne-Stokes respiration completely for two hours.

This series of observations is of interest in that it seems to show that a single injection of the compound theophylline-ethylenediamine may be more effective than its two components given separately in succession. The action of euphyllin on this patient was not so prolonged as in case 1. After the final injection, Cheyne-Stokes breathing had returned in two hours.

CASE 3. *Chronic bronchitis and hypertensive heart failure*.—An unemployed miner, aged 53. Cough, headaches, and breathlessness for five years. For six months he has had attacks of breathlessness which come on as he is falling off to sleep. These awaken him and he fights for breath till the attack passes off. There was œdema of the legs; blood pressure 170/110; heart enlarged; no murmurs; rhonchi and crepitations all over the lungs, the latter most marked at the bases; blood-urea 32 mg. per 100 c.cm.

On 22nd June Cheyne-Stokes breathing was pronounced. It was abolished by 0.60 g. euphyllin intravenously, but returned ten minutes after the injection. The action in this case was transient and the patient was not aware of any subjective improvement.

CASE 4. *Rheumatic heart disease*.—A teacher, aged 49. History of severe rheumatic fever when aged 11 but, in spite of known cardiac damage, he was capable of considerable exertion including Alpine climbing. For eight years he has been incapable of such severe exercise, and has become increasingly breathless. Five months before admission to hospital he had influenza and since then he has been orthopnoeic. The patient showed slight œdema of the ankles, enlargement of the liver, a tinge of jaundice, and engorgement of the veins of the

neck up to the angle of the jaw. Blood pressure was 128/60. The heart was grossly enlarged, with systolic and diastolic murmurs at the aortic and mitral areas. The lungs showed oedema at the extreme bases. The patient had pronounced periodic waxing and waning of respiration; he often had attacks of severe breathlessness, particularly at night, which made sleep impossible without morphine.

On 8th June an intravenous injection of 0.48 g. euphyllin was given, resulting in the abolition of periodic respiration. At the same time the patient stated that he could see better, that his mind became clear, and that his breathing became easier and perfectly steady. In his own words 'the difference in breathing was almost unbelievable'. That night he had a long undisturbed sleep without a sedative.

On 10th June a respiratory record was taken to show the effect of the two components of euphyllin. Following the injection of 0.1 g. ethylenediamine the respirations suddenly became very deep and rapid with much subjective distress and anxiety. The condition was regarded by the patient as similar to the nocturnal attacks of dyspnoea which wake him up so frequently. After about two minutes the hyperpnoea subsided, but there was no apnoeic pause, the respiration continuing in a steady regular fashion, with complete disappearance of periodicity. A few minutes later 0.6 g. theophylline was given intravenously, with no obvious additional change. After a quarter of an hour he was found to have lapsed into periodic respiration once again. A further injection of 0.48 g. euphyllin was given with the same effect as on the previous occasion, i.e., immediate subjective improvement and abolition of the periodic respiration. That night (four hours later) a stethograph record of the respiration showed no periodicity whatsoever. He had an excellent sleep for seven hours, and was even able to lie flat. Twenty-two hours after the injection the respiration was still regular, but twenty-four hours later the periodic breathing had returned.

The beneficial action of euphyllin in this patient was pronounced and maintained sufficiently long to ensure better sleep than he had had hitherto.

MODE OF ACTION

That ethylenediamine stimulates respiration was first suggested by Barbour and Hjort (1920), although acceleration of respiration from the injection of other amines had already been shown, e.g., allyl amine (Piazza, 1915). In the experiments of Barbour and Hjort there was, in addition to the respiratory action, a fall in blood pressure which would be sufficient to account for increased pulmonary ventilation, a fall of pressure in the carotid sinus producing this effect (Heymans and others, 1933). There is thus no conclusive proof from animal experiments that ethylenediamine stimulates the respiratory centre, although Vogl (1932) holds that this is the mode of action of euphyllin. He bases this view on (1) the almost instantaneous action of the drug in Cheyne-Stokes breathing, and (2) its action in rousing comatose patients to wakefulness. Guggenheimer (1932, 1933), however, maintains that the action on respiration is produced mainly by changes in the cerebral circulation, effected by dilatation of the cerebral arteries and aided by increased cardiac efficiency brought about by coronary vasodilatation. Guggenheimer's view is supported by Paul and others (1937) who regard a fall in venous and intrathecal pressures produced by euphyllin as suggestive of an improved cerebral circulation.

It is generally thought that the common underlying basis of Cheyne-Stokes respiration is depression of the medullary respiratory centres. Oxygen-lack, which has been shown by Smyth (1937) to depress the medullary respiratory centre, is probably the cause of the depression in cases of cardiovascular disease such as those described above. On this assumption depression of the respiratory centre may be abolished by euphyllin by one or both of the two suggested mechanisms: (a) a direct stimulating action of the drug on the respiratory centre, independent of circulatory changes; (b) an

increased circulation through the respiratory centre improving its oxygen supply.

(a) Direct stimulation of the respiratory centre would be expected to produce the following changes:—

1. Increased pulmonary ventilation, with resulting lowering of alveolar CO₂ tension, and lowering of the CO₂ content of arterial blood.

2. Similar changes should be demonstrable on the normally acting respiratory centre as well as on that depressed by oxygen-lack. If euphyllin caused an increased blood flow through the normal respiratory centre there would result a decreased rather than an increased pulmonary ventilation (McMichael, 1937). Hence an increased pulmonary ventilation in normal subjects would favour the view of direct stimulation of the centre.

The evidence, therefore, of a direct stimulating effect on the respiratory centre is unequivocal. Guggenheimer, however, maintains vigorously that any such action is at least enhanced by an increased circulation through the brain, and it is necessary to consider whether such an effect of euphyllin occurs. To this end we have made measurements of the more important circulatory functions as follows:—

1. *Pulse rate*.—In all cases this remained constant throughout the period of injection and after respiration was restored to normal.

2. *Blood pressure*.—There was no significant change in blood pressure accompanying the euphyllin effect.

3. *Electrocardiographic changes*.—Continuous electrocardiographic records before, during, and after injection were made in case 1. No changes were demonstrable in any of the complexes.

4. *Cardiac output*.—Using Grollman's acetylene method, with all the precautions suggested by one of us (McM.) we have measured cardiac output before and after euphyllin in one normal (J. M.) and one cardiac subject (case 4).

It is seen that there is no significant change in cardiac output with euphyllin, although the respiratory action, determined in the same experiment, was quite striking in both cases. These figures indicate positively that the effect of euphyllin on normal or Cheyne-Stokes respiration occurs in the absence of any demonstrable change in the circulation as a whole.

It might be argued that, without changing the cardiac output or blood pressure, the drug causes a selective vasodilatation of the cerebral vessels altering the distribution of blood in favour of the brain. Such an action would produce a diminished pulmonary ventilation in normal subjects, and we have seen that the opposite effect occurs. There is thus no reason to believe that euphyllin has any local effect on the cerebral circulation.

THERAPEUTIC USE AND MODE OF ADMINISTRATION

The arrest of Cheyne-Stokes breathing is not solely a matter of academic interest, for its cessation often seems to give a great measure of subjective relief to the patients. It is during the onset of sleep that periodic breathing becomes most pronounced (Harrison and others, 1934). The increased hyperpnoea may be very distressing to the patients and often keeps them awake. Restoration of normal respiratory rhythm may ensure an easy night's rest.

The drug is put up in ampoules of 2 c.cm., each containing 0.48 g. euphyllin. Vogl suggests that it should be given intravenously, and slowly. Half a cubic centimetre is injected as the respiratory movements begin to decline in amplitude, then waiting for the next period of hyperpnoea to decline the second 0.5 c.cm. is given, continuing in this manner until the whole of the 2.0 c.cm. have been injected. The danger of giving the injection rapidly is that its powerful stimulating action on the respiratory centre may be superadded to the often intense dyspnoea of the hyperpnoeic phase. An alternative method is to use the ampoules containing 0.24 g. in 10 c.cm. saline, and give 15 to 20 c.cm. of this solution intravenously, taking at least five minutes over the injection.

Suppositories are also of some value according to Vogl, but they may be effective only in mild cases. He also states that sometimes irritation in the bowel occurs from their use. Tablets by mouth may be given, but there is a general belief that theophylline may be irritating to the stomach. We have given doses up to 0.5 g. by mouth and produced the desired effect in this way, but in the event of sickness it would be better to keep to parenteral administration.

SUMMARY AND CONCLUSIONS

1. Euphyllin (theophylline-ethylenediamine) has a striking action in abolishing Cheyne-Stokes breathing.
2. Theophylline alone has no effect on Cheyne-Stokes breathing. The effect of euphyllin is due mainly to its ethylenediamine component, but euphyllin may sometimes act when ethylenediamine fails.
3. The effect is produced by a direct stimulation of the medullary respiratory centres, and it occurs in the absence of any demonstrable changes in the circulation.

Minor Rectal Pathology and its Treatment by Injection

By S. McAUSLAND, B.A. (Lond.), M.D., Ch.B.,
M.R.C.S., L.R.C.P.

(From the *Medical Press and Circular*,
1st September, 1937, p. 188)

I. INTRODUCTION

Hæmorrhoids are of much commoner occurrence than is generally supposed. Patients do not generally consult their medical attendant about this complaint until they have tried all the patent advertisements, followed the advice of all their friends, used a variety of ointments and suppositories, and even consulted osteopaths.

They avoid consulting their regular doctor in the earliest stages, fearing that he will make the dreaded suggestion of 'operation'. Fortunately the lay population is beginning to be aware of the curability of piles by a painless injection which involves no lying-up, no loss of working hours, no nursing home fees, no operation, and no anaesthetic. Thus some patients are tending to consult their doctors in the earlier stage of what they conceive to be piles. This is all to the good—for in this way sometimes an early cancer can be discovered while it is still operable; and if the condition be only one of piles, piles are more easily cured by injections when in their early stages than when the 'third degree' fissures and pruritus ani are now also amenable to injectional methods.

There is, however, among many practitioners a lack of knowledge of the minor defects of the anus and rectum—so that everything is labelled 'piles'. Many patients have been sent to me with a diagnosis of piles and with a promise of a cure by injection; and when seen, there are no piles, but there is found instead a polyp or a fissure or an external thrombosed pile, etc.

It is the object, therefore, of this paper most briefly to describe (a) minor rectal and anal pathology, and (b) the technique of the injections of internal hæmorrhoids.

II. NECESSITY FOR AND VALUE OF THOROUGH RECTAL EXAMINATION

(A) Symptoms are of great value

(a) *Bleeding*.—Internal hæmorrhoids may cause slight to copious bleeding. A fissure only causes 'a streak of blood on the paper'. A cancer may cause slight (or rarely) excessive bleeding. Black, tarry stools do not emanate from piles.

(b) *Prolapse* at stool or on exercise, is diagnostic of internal piles or of a polyp.

(c) *Constipation*: habit time: is stool hard and lumpy? (a cause of fissures).

(d) *Pain*—real pain is diagnostic of a fissure—beginning at stool and lasting for a few hours.

Prolapsed piles are only 'uncomfortable'. Of course an external thrombosed pile or a strangulated gangrenous internal pile (either with or without prolapse) is painful.

(e) *Itching*—a symptom of pruritus ani, or of external skin tags, chronically soiled with faeces. Hence the necessity for adequate washing after stool.

(f) *Mental depression* is a very common symptom—especially in males—of internal bleeding or prolapsing piles.

(B) Examination

(1) *Inspection of anus*.—A good light is essential. I find it best to lay the patient on his left side with his head low on a pillow, knees drawn up and buttocks well to the edge of the couch.

Gently separate the buttocks. The following (if present) will be obvious: pruritus ani (perianal dermatitis), external skin tags, internal prolapsed piles, external thrombosed piles, mouth of fistula. If the patient will 'press outwards', and if the operator will gently separate the sides of the anus, a posterior fissure in ano (sometimes with pus in it, sometimes with an associated 'sentinal pile') will be seen, if present.

(2) *Digital examination*.—This can easily be done with a thin finger-stall and a lubricant—provided there be no spasm (spasm is frequently present in fissure in ano). The finger must be inserted upwards and forwards, and then upwards and backwards. The insertion of the finger is more easily accomplished if the patient press outwards.

A digital examination will *not* reveal the presence of uncomplicated internal piles, but it will reveal a fissure in ano, a polyp, a strangulated or thrombosed internal pile, and a cancer. The finger should be gently inserted as high as possible.

Much care must be used in *gently* inserting a finger or proctoscope, as otherwise a fissure can thus be caused or aggravated.

(3) *Proctoscopic inspection of rectum*.—Do not use a proctoscope with a bevelled ridge. I use a Kelly's Sphincteroscope, 2½ inches long and ¼ inch diameter at its 'inspection' opening. An electric headlight is necessary and is, I think, better than having the light in the proctoscope itself: for the latter may become soiled by faeces or blood following the first injectional prick.

I insert the well-lubricated proctoscope to its full length and withdraw the obturator. Faeces can be wiped out with wool on forceps. Gradually withdraw the empty tube: if internal piles be present, they will prolapse into the speculum and can be injected (see IV below).

(4) *Barium enema*, and (5) *Sigmoidoscopic examination*.—If a cancer be suspected, but is above the area disclosed by the above rectal examination, then methods (4) and (5) should be practised. The symptoms of blood and small calibred stools are important. Loss of body-weight is generally not noticed until late in cases of cancer.

III. RECTAL AND ANAL PATHOLOGY

In this short paper I can only enumerate the conditions that may be found, without elaborating their distinctive features. If the foregoing examinational routine be carefully carried out, there will be no difficulty in making a correct diagnosis.

I shall just indicate the lines of treatment, fuller details of which can be found in my own book.

(1) *External skin tags*.—Unless painful or grossly 'in the way', these should be left alone. Scrupulous cleanliness after stool is essential.

(2) *External thrombosed hæmorrhoids*.—A round oedematous swollen 'reddy-blue' lump will be seen external to the anus covered by skin. If small (e.g., not larger than a pea) leave alone and direct the patient to bathe with cold water. Nature will absorb the clot (due to the bursting of the small perianal vein). If large or painful, clean the skin, infiltrate with 2 per cent novocaine (1 or 2 c.c. should suffice). Cut down over clot, evacuate clot, stop bleeding (if possible with pressure forceps alone); partially approximate skin edges, but do not stitch. Leave a small, raw, triangular area (devoid of skin) to granulate; thus acting as an

efficient drainage area, apex of triangle at anus. Apply pressure; bed for 4 to 8 days. Cleanliness. Healing—by first intention will result. Obviate future straining at stool by prescribing paraffin, T. D. S.

(3) *Pruritus ani*.—If there be associated internal piles, inject them. In all cases of pruritus ani, adopt the following: (a) washing after stool and at night, especially into the rugose folds of skin around the anus, which are always present; (b) application of either (1) calamine lotion made with one grain of ichthyol to the ounce, and made with 25 per cent witch hazel liquor; or (2) Percainal (Ciba), or (3) ung. phenolein; (c) avoidance of causes of localized sweat by bracing trousers and pyjamas low, and by wearing silk or cotton locally.

In mild cases the above should suffice. In severe cases the infiltration all around the anus superficially and deeply with 2 to 5 c.c. of proctocaine (or even more) will succeed. Occasionally artificial sunlight (locally) helps. Mental worry is a frequent concomitant and should be removed. I personally have not seen great results from the application of x-rays, but this is a personal opinion.

(4) *Mouth of fistula*.—This must be investigated. No injection treatment will help. The whole fistulous track must be laid open by operation. If the fistula be small and unimportant, this is no contra-indication to the concomitant injection of internal hæmorrhoids.

(5) *Fissure in ano*.—Symptoms and signs: pain, beginning at stool, and lasting for half to many hours afterwards; slight bleeding, possibly also a sentinel pile and pus (if the fissure be infected). A fissure often occurs in a neurotic nulliparous woman, but also in all classes. It is due to the passage of a hard scybalous mass which either stretches the anus (tearing it) or tears down a small piece of mucous membrane from inside the anus, which finally hangs outside, thus causing the sentinel pile. In nine cases out of ten a fissure is posterior.

(a) *Type without the sentinel pile*.—If early, this can be cured by the patient himself: soft stools to be secured by petrolagar with phenolphthalein—a small dose thrice daily before food; insertion of glycerine suppository before stool; washing gently with cotton after stool; insertion of Sanusin seimpoule (British Drug Houses) after stool. Explain to patient nature of trouble and advise him not to overstretch his anus.

If these measures fail, sterilize the outside skin, freeze posteriorly to fissure, insert gloved left index finger into anus and inject—about half an inch behind the anus—2 c.c. of Proctocaine deep to fissure and all around posterior sides of anus. The presence of pus is no contra-indication. The Proctocaine oil must be evenly distributed, not leaving large masses in any one place. The fissure will heal in nine cases out of ten.

(b) *The type with sentinel pile*.—The foregoing may be tried, and frequently (although the 'ditch' of the fissure and the sentinel pile remain) it will heal over and the patient have no more pain. He will, however, always have to keep his stools free from scybalous masses and pass soft stools, using paraffin.

In a good many old-standing cases of this type of fissure, Gabriel's operation will be necessary.

(6) *Polyp*.—Quite frequently these can be caught with forceps, pulled upon and ligatured round their base and cut off without any anæsthetic—provided they can be pulled down outside the anus. Otherwise an operation must be performed under an anæsthetic (general, local, or low spinal).

(7) *Cancer*.—If discovered a surgeon's advice must be sought.

(8) *Strangulated and prolapsed gangrenous internal piles*.—If possible replace, and get patient voluntarily to 'suck in' and 'keep in'. Suppositories are very helpful (Proctoids). In a vast majority of cases these entirely subside in two weeks; nature absorbing the clots. Rest in bed is essential. Cold water bathings are helpful. After their subsidence the remaining ordinary piles may be injected. If, however, the mass be large, operative removal is safe and advisable.

(9) *Internal hæmorrhoids*.—These are covered by mucous membrane, are formed by varicosity of the

lower hæmorrhoidal veins, and contain running blood. They are found for a distance of about two inches above the anal folds. When large they prolapse, and when the mucous membrane is thin they bleed. Their symptoms are bleeding, 'protrusion' and discomfort. They are only painful and they remain prolapsed for any length of time. Severe pain is almost always diagnostic of fissure or cancer. As stated above, mental depression is very commonly associated with internal piles, particularly in males.

IV. TECHNIQUE OF INJECTION OF INTERNAL HÆMORRHOIDS

(a) *Instruments required*.—Sphincteroscope—already described above. Two long Spencer-Wells artery forceps, for holding swabs or for the control of the very rare bleeding. Long narrow Lane's tissue forceps, for gripping a polyp. Electric headlight and battery in one's side pocket. A movable trolley, a small enamel basin, a dish of cotton-wool swabs, each about the size of a grape, sterilizer, and couch. Ten c.c. graduated syringe—Record type, eccentric nozzle. To the piston is attached a ring for the thumb, and to the cap of the syringe two rings for the index and middle fingers.

The needle is $4\frac{1}{2}$ inches long, it is bent at an angle of about 10 degrees 3 inches from the nozzle. The terminal inch and its point are gold; the remaining part of the needle is corrugated for a revolving screw cap, which, when screwed back, regulates the depth to which one can plunge the needle into the pile; and, when the syringe is not in use, the cap can be screwed forward so as to protect the point of the needle. The needle is affixed by a bayonet catch, so that on pulling the needle outwards (after injection) the needle does not become disconnected from the syringe. (My syringe can be obtained from Messrs. Alfred Cox and Sons, 152, White Chapel Road, London, E.1.)

(b) *Fluid to be injected*.—Pure carbolic acid crystals 5 per cent in pure almond oil. The dose is $\frac{1}{2}$ to 2 c.c. into each pile, and not more than 5 c.c. at any one sitting; usually not more than 3 c.c. at one sitting. Other workers have used other fluids, e.g., quinine and urethane, but I have had far greater success with the above almond oil and 5 per cent carbolic.

(c) *The actual injection*.—Instruments must all be sterilized; care must be taken especially that the point of the needle does not touch anything unsterile. An electric headlight is donned, and the patient is put on the couch, lying on his left side with his knees well drawn up, his buttocks (under which are placed cotton wool and a mackintosh) are well to the edge of the couch.

It is only necessary for the patient to expose his buttocks; he may be suitably covered from unnecessary exposure with a towel or rug—attention to such a small point of etiquette is pleasing to a patient, especially of the female sex.

The well-greased sphincteroscope is introduced to its full extent and the obturator removed. Then the sphincteroscope is somewhat withdrawn, pushed in slightly again, and so on, until the piles are in view; having prolapsed in the speculum. The rectum should be empty or swabbed until empty. With forceps in the right hand, swab the field with cotton-wool dipped in lukewarm water (to which is added a drop or two of lysol), holding the sphincteroscope all the while in the left hand. Then pick up the sterile syringe, ready loaded with the fluid, and insert the needle into the lowermost pile. It is better to inject first the bottommost pile in the speculum and then the other piles, if indeed it be intended to inject all at one sitting. If the biggest be injected it will occupy the whole himen, blocking the others from view; personally I consider that not more than three places should be injected at one sitting.

The needle must be inserted into the pile, i.e., a bulging part covered by mucous membrane; if this be done the patient should not feel the needle prick. Avoid any obvious vein. It is essential that the needle be inserted into the centre of the pile mass; the feeling to the operator should be like plunging the needle into the midst of a jelly. If anything harder be encountered

the needle should be withdrawn. Then inject slowly; gradually the pile will go whitish and swell up; it is much better to inject too little (especially at the first sitting) than too much. Stop when the pile begins to swell and to go 'whitish', or even before that.

An average injection per pile will be from 1 to 2 c.c. of the oil, but experience in time decides each case; $\frac{1}{2}$ c.c. is a safe small dose. Hold the needle in position for one to two minutes, then withdraw it slowly. On the removal of the needle sometimes a slight ooze of oil from the puncture will be noticed; a slight bleeding may also occur. These cease when the speculum is removed.

It is very rarely (especially with the oil treatment) that bleeding is troublesome; very rarely a bleeding point has to be squeezed by the long artery forceps, and pressure for one minute suffices in all cases without any ligature. This pressure is not felt by the patient, who does not, in fact, know what is going on, for his pile is anaesthetized by the carbolic. The injections having been made, the sphincteroscope is removed, preferably by first re-inserting the obturator; and after the patient's external anal region has been cleansed, and after two or three minutes on the couch, he can get up and go home.

The whole operation is performed in less time than it takes to describe. There is no pain to the patient, his only slight discomfort is the introduction of the speculum; and, if it be well lubricated, its introduction is no more painful than putting one's finger into one's mouth.

The essential practical points are, therefore, do not inject too much, do not inject too low, and only inject into an internal pile, and not into healthy rectal wall. Always inject through the speculum, and never inject an internal pile while it is prolapsed.

(d) *After-effects and results.*—It is best for the patient to rest in the recumbent position for about three hours on his return home. About 85 per cent of patients experience an aching in the rectum which lasts for three to four hours; 10 per cent have no discomfort at all; and in about 5 per cent of cases the pain is severe—lasting for twelve hours. Patients should be directed to 'draw inwards', and to keep their piles inside. If they should prolapse after injection they should be bathed with cold water and replaced by the patient. I generally insert a 'Proctoid' suppository after injection. The patient can do his usual work on the day after the injection, but unnecessary or strenuous exercise should be interdicted for three or four days. Patients should take paraffin or Agarol three times before meals during treatment; bowels may be moved on the day after injection.

In 90 per cent of cases the patient will return for the next injection (in a fortnight's time), stating that there has been no bleeding and no protrusion, and with marked signs of gratitude.

Injections should be continued until no more prolapse can be seen within the inserted speculum. An average case of first degree piles (which bleed but do not prolapse) can usually be cured in three visits; a case of second degree (piles which bleed and prolapse, but which can be replaced and kept replaced), in four or five visits. Third degree piles are sometimes better operated on, but even here great improvement can be effected by injection. Experience here will decide: there are really exceedingly few cases that need operation.

If the patient will always henceforward attend to his after-care and rectal toilet and hygiene, the cure by injection is as permanent as with surgical removal. The patient must be directed to practise quickly, 'pressing in and out' several times daily for the rest of his life (beginning a few days after injection). Regular habit time. Soft stools—secured, if possible, by brown bread and fruit and exercise, otherwise by paraffin or Agarol. Washing after stool.

V. SUMMARY

In this paper rectal pathology has been described, together with a simple but exhaustive method of rectal examination. Apart from the treatment of cancer and

certain cases of fistula and fissure which need operative treatment, all cases can be dealt with by injectional and other means—all within the scope of general practice.

In particular, an injectional method is described whereby bleeding or prolapsing internal piles can be cured safely, quickly, painlessly and cheaply; with no lying-up on the part of the patient, no risk of anaesthetic, no loss of wages, no nursing home fees; and the gratitude of the patient is extreme.

The Milk Problem : A Critical Study of its Nutritional, Hygienic, Economic and Social Aspects

By H. C. BENDIXEN, G. J. BLINK, J. C. DRUMMOND, A. M. LEROY, and G. S. WILSON

(Abstracted from the *Bulletin of the Health Organization, League of Nations*, Vol. VI, No. 3, June 1937, p. 371.)

NUTRITIONAL

1. A distinction is drawn between animals with a high milk-producing capacity and animals producing milk with a high butter-fat content. Both these characteristics are desirable, and are found together in certain stocks.

2. There is an important relationship between the number of cows in the herd and the cleanliness and safety of the milk produced. A farmer possessing a small number of cows yielding a considerable quantity of milk is in a better position than a farmer possessing a larger number of cows yielding a smaller quantity of milk. In the first place, he will spend less time over the actual milking and will therefore have more time in which to attend to the sanitary conditions of production. In the second place, the smaller the number of cows there are in the herd, the less likely is disease to spread if it is introduced, and the less costly will be the replacement of diseased animals.

3. In general, too little attention is being devoted to the proper feeding of dairy cows. Without an adequate diet, the cow, however carefully selected, cannot produce the maximum quantity of milk and butter fat of which she is capable. An output in any one month more than 10 per cent less than that in the preceding month strongly suggests that the diet of the animal needs readjustment.

4. There is at present a considerable difference to be found in the data contained in the feeding charts for milch cows in various countries. To avoid unnecessary confusion, it would be of value if an agreement could be reached between scientific and practical experts on the food units to be recommended. In this connection, the method of forage equivalents seems to have strong claims for general adoption.

5. There is a close relationship between the constitution of the animal ration and the value of the milk as a human food. In order to secure milk with 'protective' properties, producers should include in the diet a sufficiency of vitamins A and D, particularly during the winter months. This may be done by providing the animals with ensilage, feed carrots, dried grass prepared under conditions involving no loss of carotene, and, if necessary, with vitaminized products, such as irradiated yeast.

6. For many reasons, it would be desirable to produce a milk of standard nutritive quality for consumption in any given country. The definition of such a standard is open to discussion. The main nutritive qualities of milk for human beings are the following:—

- (a) The fat content, which has the greatest influence on the energy value of the milk;
- (b) the nitrogen content, which is of extreme importance in human physiology;
- (c) the content in mineral salts, which is of particular importance for the proper development of the growing child;
- (d) the vitamin content, which is likewise of considerable importance in growth and in the prevention of disease.

There is a close relationship between the fat content and the nitrogen content of the milk and there is therefore a strong reason for producing milk with a high fat content. For human consumption, however, such a milk is not altogether desirable, partly because it may cause indigestion in infants and young children, and partly because the increased cost of its production must necessarily be reflected in a higher cost of sale. A milk with too low a fat content is also undesirable, partly because it is too poor in nitrogen, and partly because it conduces to fraud by the producer or the distributor. Clearly a compromise has to be reached, and at the moment we are of the opinion that producers should concentrate on producing milk with a fat content of between about 3.5 and 4 per cent. If it should be found later that the vitamin A and D content is highly correlated with the quantity of fat, it may be necessary to reconsider this recommendation and raise the maximum quantity of fat desirable.

7. The more extensive use of *separated milk* has been advocated by the Technical Commission on Nutrition of the League of Nations Health Organization. At present, large quantities of this type of milk are available at butter factories at a price that is extremely low. Since separated milk contains the nitrogen, carbohydrate and mineral fractions, it has a very high nutritive value for human beings. At first sight, therefore, there is a strong case to be made out for its increased consumption. On further examination, however, difficulties appear in the practical realization of this policy.

So far as large towns are concerned, the difference in cost to the consumer between whole and separated milk will not be very great. Approximately 50 per cent of the retail price of whole milk is due to transport, processing and distribution charges. The same charges will be necessary for separated milk, and, by the time it reaches the consumer, its cost will probably be not more than 40 per cent below that of whole milk. For this price, the consumer will receive a milk with only 54 per cent of the calorific value of whole milk. It may be pointed out that the whole tendency of modern milk production is to concentrate on the provision for the public of only one or two classes of milk. In this way, it is possible for the large distributing companies to cut down their costs, and so supply the public with a good quality whole milk at a price less than would be possible if several different grades had to be provided.

The cost might be somewhat reduced if the milk could be filled into quart-size bottles, and distributed to certain centres where the people could come and collect the milk themselves. Under these conditions, it is estimated that, in London, separated pasteurized milk could be provided at 3d. a quart—approximately half the price of whole milk.

Since, as already mentioned, separated milk has only a little over half the calorific value of whole milk, the only justification for advocating its sale would be to encourage the purchase of separated milk by those who otherwise would buy no fresh milk at all. If the poorer sections of the population could be educated to give separated milk as a drink to their children in place of tea flavoured with condensed milk, and to use separated milk in considerable quantities in the preparation of cocoa, rice puddings, and so on, then a very real benefit might result. It is difficult to tell, however, whether separated milk would find a ready sale. Our own opinion is that the experiment is worth trying.

If it is objected that the dietary of such persons will contain too little butter fat, it may be observed that it is much cheaper to buy butter fat in the form of butter than in the form of liquid milk. In Great Britain, for example, one pound of butter fat costs 2s. 8d. in liquid milk and only 1s. 10d. in butter, or even less if Empire butter is used.

In country districts and in small towns, the transport costs would be, as a rule, very much less, though it might be difficult to arrange for adequate pasteurization of the separated milk to be carried out.

An alternative method would be to supply separated milk in dried form. Since the milk could be processed at the butter factory itself or in its near neighbourhood,

the heavy transport charges of the liquid milk would be avoided. The final product would have a high nutritive value, would contain in almost undiminished quantity the very important B₂ (lactoflavin) vitamin, would cost remarkably little, could be used for a variety of purposes, and would be less liable to compete with whole milk than when distributed in liquid form. The strong objection, however, of most people to the slight trouble involved in preparing dried milk for the table would probably result in its restriction to special centres, schools, kitchens and institutions.

HYGIENIC AND ECONOMIC

8. It is important to distinguish between the terms 'clean' and 'safe' in relation to milk. *Clean milk* is milk that is free from extraneous matter, such as manure and dust, from blood, and from an undue number of leucocytes and bacteria. *Safe milk* is milk that is free from bacteria capable of giving rise to disease in man or animals. For human consumption, milk ought to be both clean and safe.

9. In general, production of milk on the farms should be under agricultural and veterinary supervision, and distribution of milk under medical supervision. On the farms, the agricultural authorities should supervise the cleanliness of milk production, and the veterinary authorities should ensure as far as possible that the milk is supplied only by healthy animals. Once it has been produced the milk should be supervised by the medical and sanitary authorities, who should watch over the whole process of distribution.

10. In order to obtain the best results, the various activities of the agricultural, veterinary and medical authorities should be closely integrated. Probably the best method of arriving at this end would be the establishment in each country of a Permanent Milk Commission, preferably on a national basis. Such a commission should comprise not more than six or eight persons, representing the interests of producers, distributors and consumers, as well as of the agricultural, veterinary and medical professions. Among the more important duties of the Commission would be the endeavour to harmonize the conflicting interests of the milk industry, to do everything in its power to improve the quality of the milk supply, and to draw up a national milk policy designed to eliminate wasteful methods of production and distribution, and so provide the public with a plentiful supply of clean and safe milk at the lowest possible cost. In some countries, it might be advisable to establish sub-commissions on a regional or municipal basis, in order to exercise control over the production and distribution of milk in their areas.

11. The production of clean milk depends more on scrupulous care in technique than on the possession of expensive buildings and equipment. Nevertheless, a good technique is difficult to maintain without adequate facilities, and the production of clean milk must always entail a certain minimum expenditure both in outlay and in running costs.

12. Unsterilized utensils contribute more than any other single factor to the bacterial contamination of milk on the farm. Special care should, therefore, be devoted to the proper sterilization of milking equipment, either by steam or by chlorine.

13. Dairies and collecting stations that receive milk in churns should return these churns to the farms in a properly cleansed and sterilized condition. In some countries, particularly in districts where the milk is made into butter, it is a common practice to remove the cream and return the separated milk and butter milk to the farmer in the churns in which the whole milk was received. Similarly, in cheese-making districts, the whey is often returned to the farm. Since the separated milk, butter-milk or whey is usually swarming with bacteria by the time it reaches the farm, the churn containing it is not in a fit condition to receive a fresh supply of whole milk. The remedy for this particular state of affairs would appear to be the provision of a double set of churns, one for the whole milk and one for the by-products.

14. Far too little attention is being paid to the cooling of milk on the farm. No matter how carefully it is produced, milk should be cooled immediately after leaving the cow to as low a temperature as possible. Unless milk is cooled, and kept cool, bacterial proliferation will take place, the keeping quality of the milk will diminish, and toxic products may be formed, even by non-pathogenic bacteria, that are capable of giving rise in infants and young children to gastric disturbance and diarrhoea.

15. In most countries of Europe, extensive disease prevails among the cattle. So far as milk hygiene is concerned, the three most important diseases are tuberculosis, contagious abortion and mastitis. Generally speaking, the spread and gravity of these diseases have gone hand in hand with the development of intensive milk production.

16. Milk frequently contains pathogenic organisms derived from (a) the diseased udder of the cow, or, occasionally, the cow's faeces or uterine discharge; (b) a human case or carrier, the infection usually coming from the nasopharynx or the intestine, and gaining access to the milk by sneezing, coughing, etc., or by contaminated fingers; (c) a contaminated water supply; (d) sometimes perhaps from rodents.

17. For a large number of reasons, the extent of milk-borne disease is extremely difficult to ascertain, and all our estimates probably err greatly on the conservative side. In any country, the amount of recognized disease is proportional to the zeal with which it is sought for.

During the years 1912-1935, records are available in Great Britain of the occurrence of 103 milk-borne outbreaks of scarlet fever, septic sore-throat, diphtheria, typhoid fever, para-typhoid fever, dysentery and gastro-enteritis, affecting about 12,000 persons. During the same time, it is estimated that about 150,000 persons contracted tuberculosis of bovine origin of which over 60,000 died, while an unascertained number, probably several thousands, suffered from undulant fever due to infection with *Br. abortus*.

Our information for other countries is even less complete than that for Great Britain, but, such as it is, it points to the existence of a considerable amount of milk-borne disease, much of which is at present being overlooked. In Denmark, for example, where serious attention has only recently been devoted to the investigation of this problem, approximately 10 per cent of all deaths from tuberculosis appear to be due to infection of bovine origin. About 500 cases of undulant fever occur annually, of which a considerable proportion is due to the consumption of infected milk. In addition, during the three years 1934-36, nine outbreaks of epidemic milk-borne disease have occurred, affecting over 10,000 persons.

Over and above these well-recognized infections, there are a number of other milk-borne diseases in which intoxication rather than infection appears to play a major part. Such conditions comprise epidemic nausea and vomiting, some types of acute gastro-enteritis, and summer diarrhoea of children. With the exception of certain cases in which the toxic principle is derived from the cow's food, these conditions appear to result largely from the inordinate growth in the milk of certain relatively non-pathogenic bacteria.

18. Butter and cheese probably play very little part in milk-borne infections, the great majority of which are due to the consumption of raw milk and cream.

19. Attempts to render milk safe for human consumption may be considered under three headings: (a) control of animal disease; (b) control of the human personnel; (c) destruction of pathogenic organisms in the milk by pasteurization or other form of heat treatment. These may be considered *seriatim*.

20. *Control of animal disease.*—(a) Whenever possible, the eradication method should be used. The general principle of this method consists in the detection and elimination of all infected animals—not merely of those that are obviously diseased—and the building-up of a healthy herd from the young, non-infected stock.

(b) Any campaign to eradicate animal disease should be carried out in the economic interests of the farmer, and should be based on the assumption that a healthy herd is more profitable than a diseased herd. As a rule, State subsidies will be required. Bonus payments to the producer for milk from disease-free herds afford an excellent stimulus to the farmer, but on no account should the conduct of the campaign be made contingent on the payment by the consumer of a higher price for milk from such herds.

(c) The amount of animal disease is so extensive, and the difficulties of combating it are so great that, except in certain limited areas, there is no hope in our generation of providing the human population with milk from healthy herds. However desirable, therefore, the control of animal disease may be on other grounds, it cannot be regarded as affording an immediate solution to the public health problem of protecting the consumer against the risk of milk-borne disease.

21. *Control of the human personnel.*—The part played by medical inspection of the human personnel handling the milk is in many ways analogous to that of routine veterinary inspection of the animals producing the milk. Even when carried out thoroughly, with concurrent bacteriological examination, it can never be trusted to detect all cases and carriers of infectious disease. There are, however, conditions in which medical inspection of the personnel is indispensable; for instance, where the milk is to be drunk raw, medical and bacteriological control of all persons handling the milk in the course of its production and distribution should be insisted upon. A similar control should likewise be exercised over all human operatives in pasteurizing or other plants in which large volumes of mixed milk are being handled, so as to prevent any possible danger of contamination of the milk after processing.

22. *Destruction of pathogenic organisms in milk by pasteurization.*—No raw milk can ever be regarded as completely safe for human consumption. Even if produced from healthy animals, milk is so subject to contamination from human and other sources that it must always be regarded in the raw state as a potentially dangerous article of food. The only satisfactory method of ensuring the final safety of the product is to submit it to some form of heat treatment that can be relied on to destroy any pathogenic organisms that may be present. *It is our considered and emphatic opinion that all liquid milk for human consumption should be adequately pasteurized or boiled.*

The term 'pasteurization' covers a number of different processes. Whichever process is used, it is desirable that (a) the milk for processing should be produced under hygienic conditions, and should conform to a given pre-pasteurization standard of bacteriological cleanliness; (b) the processing should be carried out in properly designed apparatus, free from structural and mechanical defects, by skilled and conscientious operatives who fully understand the rationale of the method they are using; (c) the operatives themselves should be under medical and bacteriological supervision so as to avoid the possibility, through negligence or a mechanical breakdown, of contamination of the bulked milk from a human case or carrier; (d) the efficiency of the processing should be controlled by suitable chemical and bacteriological tests; (e) after pasteurization, the milk should be cooled to a low temperature and filled automatically into sterilized bottles or other containers which are immediately sealed; (f) the milk should be kept cooled or refrigerated until its delivery to the consumer; (g) at the time of delivery it should conform to a given standard of bacteriological cleanliness; (h) the whole process should be carried out under the strictest supervision of the medical and sanitary authorities. Under these conditions pasteurized milk can be guaranteed to be safe for human consumption. At the present time, in many countries, the control over pasteurization is far too lax. If pasteurization is to be recommended as the chief measure for protecting

the public from milk-borne disease then no effort must be spared to ensure that the process is carried out efficiently and that subsequent contamination of the milk is avoided.

24. Though many pseudo-scientific objections have been advanced against it, we have been unable to find any that is supported by adequate evidence. On the other hand, there is a considerable amount of evidence to show that, when pasteurization has been introduced on a large scale, milk-borne disease has been practically abolished. There is reason to believe that, if pasteurization was rendered compulsory for all towns, infection derived from milk would be completely prevented. In country districts, where compulsory pasteurization is impracticable, insistence should be laid on the necessity of boiling milk prior to consumption.

25. Where there is a special demand for raw milk this should be satisfied by the provision of milk which is derived from herds free from tuberculosis, contagious abortion and mastitis, and which is produced and distributed under stringent veterinary and medical control.

26. Careful consideration has been given to the minimum hygienic requirements for milk destined for human consumption.

There are two main questions involved. On the one hand, it is desirable to provide the public with the maximum quantity of milk at the lowest possible cost. On the other hand, it is essential to take the strictest hygienic precautions in the production and distribution of milk if milk-borne disease is to be avoided. It might be thought at first that there is a sharp antagonism between these two proposals, but this is more apparent than real. Experience in many countries has shown that a well-organized company can collect, pasteurize, bottle and distribute milk of a high standard of cleanliness and safety at a cost only slightly in excess of that demanded by the small producer who sells his own milk unbottled and in a potentially dangerous condition. Though bottling undoubtedly increases the cost of milk to a slight extent, it has very great compensating advantages. Not only does it conduce to greater cleanliness and safety, but it tends to reduce the number of milk distributors in any town or district, and thus to eliminate the wasteful overlapping that at present so frequently occurs. We are of the opinion that the right course to pursue is to concentrate on the production and sale of milk under good hygienic conditions. This will involve a demand for clean milk production, pasteurization and bottling. Such a policy will, we believe, be successful in increasing the quantity of milk consumed by the public, since the guarantee of security that it will afford will more than counterbalance the slightly lower price at which dirty and often unsafe milk is sold in many cities. Loose unbottled milk, besides being unhygienic, opens the way to fraudulent practice, and the loss suffered in this way by the small consumer may be greater than the slightly increased price that he will have to pay for properly bottled milk.

27. The milk of producers should be graded and paid for on the basis of quality—fat content, cleanliness, and freedom of the herd from disease. No substantial improvement in the quality of the milk supply is to be expected unless an economic stimulus is afforded to the producer for the extra trouble and expense involved. In order, however, to avoid the difficulties of isolated bonus systems and of fraudulent practice among buyers, it is important that *all* milk should be paid for according to its quality, and that the payment should be under the control of a regional or national Milk Commission.

28. Milk for consumption, on the other hand, should not be graded. The best milk available should be directed to the liquid market, and only this milk should be offered to the public. Grading of producers' milk is highly important; grading of milk for consumption has no particular value, and merely confuses the public. The sale of milk under special names,

such as children's milk, certified milk, preference milk, tuberculin-tested milk, and so on, should be discontinued.

29. All milk for human consumption should be placed under much more rigorous laboratory control than is at present generally practised. In general, the milk of every producer should be tested at weekly intervals for bacterial cleanliness by a simple test such as the modified methylene blue reduction test. Summer and winter standards of cleanliness should be laid down, and any producer whose milk fails to reach the given standard in at least 75 per cent of tests throughout the year should be prevented from supplying milk to the liquid market. Pasteurized milk furnished by distributors should be tested even more frequently in order to maintain a high standard of processing. For this purpose, the phosphatase test appears to be best suited for the control of holder-pasteurized milk, and the Scorch test for milk pasteurized at a high temperature. Distributors whose milk is shown to be inadequately pasteurized on more than exceptional occasions should have their licence revoked.

30. In general, the producer pays too much attention to the selling price of his milk and too little to his costs of production. This applies particularly to countries like Great Britain, which do not have to compete with other countries in the export market. There appear to be several possible ways of lowering the costs of production, and we recommend that producers should devote serious attention to this subject. There is reason to believe that if the cost of liquid milk could be appreciably lowered, there would be a substantially increased demand for it.

31. So far as towns are concerned, the distribution of milk including such operations as collection from the farms, cooling at a central receiving depot, transport to the town, pasteurization, cooling, bottling, refrigeration and final delivery to the home of the consumer is rapidly assuming an importance far greater than that of simple production. A large distributing business has to arrange for the disposal of surplus milk, and may have to build its own factories to turn it into butter, cheese, condensed milk, dried milk, and so on. Distributors of this type can no longer be regarded as simple middlemen; they constitute an essential part of the dairy industry. The efficient distributor is often faced with unfair competition from other less efficient firms. The most satisfactory way of avoiding this is by the introduction of legislative measures, which not only insist on a high standard of quality of the final product, but which lay down definite hygienic requirements to be complied with during the actual process of production.

32. We believe that the future of the dairy industry lies in the gradual elimination of the small and often inefficient distributor, and its concentration into the hands of large, well-organized firms which are making use of every aid that science can offer them to improve the technical efficiency of their business and the high quality of their products. Just as during the past century the water supply of our large towns has passed out of the hands of multiple small producer-retailers into the hands of large concerns, controlled by the municipality, a public utility company, or some similar body, so, in the future, we believe that milk for human consumption in the liquid state will come to be regarded more and more as an article of food over which such care has to be exercised that none but large and efficient organizations will be allowed to handle it.

SOCIAL

33. Any nutrition policy designed to secure a rational diet for the population as a whole, and hence to adapt the consumption of milk and milk products to the requirements of health, must be based on a detailed study of family budgets. The place of milk in any such nutrition policy must depend on the nature and quantity of other articles in the dietary.

34. The consumption of milk and milk products increases directly with the size of the income and inversely with the number of members in the family.

35. So long as the relation between prices and the purchasing power of various population groups renders it impossible for everyone to obtain sufficient milk and milk products, so long will social measures be necessary to ensure a greater consumption of these articles, particularly by pregnant and nursing women, infants, children of pre-school and school age and unemployed or indigent persons. Among the various measures to increase milk consumption, we recommend the grant by the State of subsidies for the provision of milk to schools, to pregnant women,

nursing mothers, etc.; facilities for the provision of milk in factories, offices, restaurants, railway stations, etc., and the encouragement, by the institution of school meals, such as the so-called Oslo breakfast, of an increased consumption of other dairy products, particularly butter and cheese. Of these measures, we regard the milk-in-schools scheme and the Oslo breakfast as worthy of special commendation.

36. Though propaganda may have some value in increasing consumption, we believe that its effect is liable to be over-estimated. The best possible method of propaganda is the provision of a supply of clean and safe milk in which the public can have perfect confidence.

Reviews

PRACTICAL PROCEDURES.—Edited by Sir Humphry Rolleston, Bt., G.C.V.O., K.C.B., M.D., F.R.C.P., and A. A. Moncrieff, M.D., F.R.C.P. 1938. Published on behalf of The Practitioner (5, Bentinck Street, W.1.) by Messrs. Eyre and Spottiswoode (Publishers), Limited, 6, Great New Street, E.C.4, London. Pp. 293. Illustrated. Price, 10s. 6d.

In his introduction to this book Sir David Wilkie takes the view that the general practitioner of to-day is tending to encroach on what were hitherto the preserves of the specialist, and is now beginning to carry out special procedures himself. This is a very healthy sign for the practice of medicine in the future, as there was a distinct danger that the practitioner would become little more than a sorting clerk or guide to direct people to the right kind of specialist. Twenty-five years ago the physician, even the fashionable London physician, seemed to be afraid to use a serum syringe; just before the war the reviewer knew an eminent pathologist, the most remunerative part of whose practice consisted in giving neosalvarsan to patients sent to him for the purpose by both physicians and surgeons.

Some of the titles of the chapters in this book are 'Plaster of Paris Technique', 'Indications and Technique for Blood Transfusions', 'Estimation of Blood Pressure', 'Local Anaesthesia', and 'Lumbar Puncture in General Practice'; this gives one an idea of its scope and value to the practitioner. Each chapter is contributed by a well-known specialist, physician or surgeon, who has had a wide experience with the particular 'practical procedure'.

The chapter on blood transfusion is a comprehensive one including details of blood grouping and direct matching, as well as the actual technique of the transfusion. The writer favours the giving of citrated blood and thinks that the advantages claimed for giving whole uncitrated blood are doubtful and certainly not commensurate with the difficulties and dangers. Dr. Lionel Whitby writes on the interpretation of blood examinations and on the technique of blood counts. He mentions the halometer and issues a warning that its use does not constitute a short cut to the diagnosis of anaemias and that it is not a substitute for the haematocrit: we agree but should have expressed it more strongly.

We do not feel confident that Sir David Wilkie's optimism regarding the practice of medicine is as applicable in this country as it is in Great Britain to-day, but we hope it will be so very soon, and, if this useful little book is read widely, it will certainly do much to hasten this healthy change in general practice in India.

MEDICAL DIAGNOSIS. THE GENERAL PRACTICE SERIES.—By S. L. Simpson, M.A., M.D. (Camb.), M.R.C.P. (Lond.). 1937. H. K. Lewis and Company, Limited, London. Pp. ix plus 244. Price, 10s. 6d.

As the name of the series suggests, this book is very much more suited to the practitioner than to the

student. Again, even for the practitioner it is more valuable for general reading than as a reference book.

The book is divided into chapters in which for the most part one 'system' is dealt with, but there are other chapter headings such as 'Specific Infectious Fevers' and 'Children'. In each chapter, after a short introduction, each disease state is given a small section with a clear heading, such as colitis, diverticulitis, renal calculus, encephalitis lethargica, splenic anaemia, etc., but there are also symptomatic headings, such as diarrhoea, constipation, and vertigo; this doesn't seem quite consistent.

However, the book provides quite pleasant and very informative reading for the physician who wishes to improve his diagnostic acumen.

PHYSIOLOGICAL PRINCIPLES IN TREATMENT.—

By Sir Walter Langdon-Brown, M.A., M.D. (Cantab.), D.Sc. (Oxon.), F.R.C.P., and R. Hilton, M.A., M.D. (Cantab.), F.R.C.P. Seventh Edition. 1936. Baillière, Tindall and Cox, London. Pp. ix plus 308. Price, 10s. 6d.

WHEN we say that this very important book is outdated, we hope that we shall not be misunderstood. Before saying what we do mean we should perhaps say two things that we do not mean; we do not mean that the teaching is out of date in this seventh edition—on the contrary, the book has been completely revised, rearranged, and many chapters have been rewritten: nor do we mean that the mode of approach of the subject is old fashioned and that the book has outgrown its usefulness.

Modern scientific medicine with the help of physiology is advancing along two roads which both lead in the same direction: (a) we are continually applying physiological facts, newly discovered, in our practice, and making remarkable advances in diagnosis and treatment; on the other hand (b), we are continually sending empiricisms to the physiological laboratory for the rationale to be worked out and thereby finding out new physiological facts which will often lead to simplification or elaboration of the empiricism, in either case much to its advantage. As medicine is much older than physiology, empiricism was for a long time the order of the day and the advances first made were along the old road (b), but as time goes on the new road (a) must inevitably become the more important thoroughfare. To-day, the traffic is fairly evenly divided: thirty years ago when the first edition of Sir Walter's book was published, the new road was scarcely opened and even the old road was not so well used as it is to-day, now that—to maintain the metaphor—the country beyond has been opened up and popularized.

Sir Walter and his book played no small part in bringing about this closer association between physiology and the practice of medicine; the textbooks of medicine of to-day contain much more physiology and those of physiology much more medicine than was the case when the first edition of this book was published. Further, Sir Walter has had many imitators, some of

their books are more comprehensive and many of them successful.

However, though its conception is no longer unique, the book still has many unique qualities, and no physician could fail to gain much in the way of practical knowledge from its perusal. We commend this book strongly to the notice of all practising physicians: for those who are familiar with the early editions, we will add that there is sufficient important new material in this edition to make it well worth re-reading.

L. E. N.

AN INTRODUCTION TO MEDICAL SCIENCE.—By W. Boyd, M.D., M.R.C.P. (Edin.), F.R.C.P. (Lond.), Dipl. Psych., F.R.S. (Canada). 1937. Henry Kimpton, London. Pp. 307. Illustrated with 108 engravings. Price, 16s.

ONE cannot fail to admire both the courage and the energy of the author in undertaking the writing of this book. It is far harder to write down to the level of comprehension of a medically-uneducated public, successfully, than to write on a highly technical subject that one has not completely mastered, and 'get away with it'. The 'popular' medical book is usually written by a professional writer, who, if he happens—which is unusual—to be a medical man, has probably been an unsuccessful one, and is therefore suspect. Here, however, the case is quite different; the writer is a most distinguished pathologist, so that when one encounters statements that appear to be inaccurate, one at least knows that they were not made through ignorance, but are often the inevitable result of necessary simplification of language.

Under the heading of 'undulant fever', the author writes 'This disease is caused by a very small organism midway in form between a coccus and bacillus. For this reason it is called neither, but is given the name of its discoverer, Sir David Bruce, and is known as *Brucella*'. Had the italicized portion (our italics) been omitted we feel that the kindergarten atmosphere would have been removed without any loss of clarity. There are many such examples.

The statement that it is necessary to give quinine for several months to eradicate the malarial parasites 'from the spleen' is misleading. The author missed a great opportunity for picturesque generalization in not giving the modern classification of the anæmias.

The book appeals to us far more as one for nurses, technicians, non-medical missionaries, and possibly doctors' wives (the book is dedicated to E. B.), than as one either to recommend or lend to patients (in the reviewer's experience average American patients already know far more than this book could teach them, and are no better, as patients, for their knowledge!) or for the pre-medical student, who would later have to do a certain amount of unlearning.

PHYSIOLOGY IN HEALTH AND DISEASE.—By C. J. Wiggers, M.D. Second Edition. 1937. Henry Kimpton, London. Pp. 1124. Illustrated with 191 engravings. Price, 42s.

THE success of the first edition of this book, which was exhausted so rapidly that it enabled a second edition to be issued after so short an interval as two years, is a sign of the times and indicates the existence of a much closer liaison between the physiologist and the physician than there has ever been hitherto. Though we have some excellent standard textbooks of physiology which will always be in demand, it is books of this type that should be the textbooks of the medical student in the future, and the time separation in the teaching of the physiology of health and of disease, respectively, should disappear; this at least presents one way of cutting down the curriculum.

In this new edition, no very extensive changes have been made, but there has been a certain amount of rearranging of matter, necessary additions, and a few corrections.

The writer has a clear and easy style which makes reading a pleasure, though now and then the sparing

of commas makes it necessary to read a sentence more than once before its meaning is grasped.

Though sneering at the mistakes of our predecessors is out of place in any scientific book, now and then a little mild cynicism adds a piquancy to their perusal; for example, in discussing the classification of the anæmias the author writes 'The common classification of clinical anæmias into primary and secondary forms is only of historical interest and reminiscent of the day when it was believed that some anæmias are the result of (secondary to) causes which are or ought to be discoverable, while primary anæmias are due to some essential change in blood cell physiology which might defy the insight of man'.

The statement that the anti-pernicious-anæmia factor is produced in the pyloric mucosa was certainly justifiable when it was written, but may have to be revised in view of more recent work on this subject.

This new addition is, we foretell, likely to be as popular as the first: it certainly deserves to be.

BABY'S POINT OF VIEW: THE PSYCHOLOGY OF EARLY BABYHOOD.—By E. J. Partridge, F.R.C.S., L.R.C.P. 1937. Oxford University Press, London. Humphrey Milford. Pp. 84. Price, 2s. 6d. Obtainable from Oxford University Press, Bombay and Calcutta

THIS small book explains to the modern mother the findings of psychologists in regard to the emotional development of infancy. It stresses the psychological need for breast feeding and the psychological injury inflicted on infants by separation from their mothers. The feeling of safety and the feeling of being loved are the primary needs of the infant. The author stresses that these needs can only be fully met by the mother herself and that even the youngest infant recognizes and resents a substitute. The author condemns the too harsh discipline that is commonly imposed on infants in western countries and believes this discipline to be a frequent cause of neurotic illness in adult life.

Whether this be so or not, this small volume should prove a valuable corrective to those brought up in a too strictly disciplinarian school of thought. In this country the effects of lack of discipline are more commonly seen than those resulting from a too strict and harsh regime. Observation leads one to the conclusion that children must learn to accept a certain discipline if they are to develop satisfactorily. This discipline ought of course to be imposed in a way that will arouse as little resentment as possible in the child's mind. Mothers, however, need not always be blamed if feelings of resentment are aroused in their children, for some infants demand so much from their mothers that the complete fulfilment of their demands is impossible; even the gentlest treatment may arouse feelings of resentment in infants born with this diathesis. This point is not raised by the author who tends to lay an undue burden of responsibility on the mother who may in consequence blame herself unduly should her child develop a neurotic illness in later life.

J. B.

A MANUAL OF TUBERCULOSIS FOR NURSES AND PUBLIC HEALTH WORKERS.—By E. Ashworth Underwood, M.A., B.Sc., M.D., D.P.H. Second Edition. 1937. E. and S. Livingstone, Edinburgh. Pp. xix plus 404. Illustrated. Obtainable from Messrs. Butterworth and Company (India), Limited, Calcutta. Price, Rs. 6-6

WE welcome the publication of the second edition of Dr. Underwood's little book on tuberculosis, the scope of which has now been widened in order that it should appeal not only to the nurses, but also to the class of persons such as almoners, sanitary inspectors and other health workers. In view of the recent developments on the subject there have been considerable additions and alterations in this edition. Chest surgery has been dealt with in a separate chapter. The last three sections are entirely new; they have been added to assist those who have to deal with the administrative side of the subject.

The subject of tuberculosis has been dealt with in a very comprehensive manner. The summaries at the end of the chapters and the glossary at the end of the book are good and useful.

Some of the material included is really unnecessary, such as the operation of shaving the beard and that of hair-cutting of male patients; two full pages are too much for this purpose. Brevity, obviously necessary for a book of this type, has at times led to slight inaccuracies, such as are found in connection with the Mantoux test and the preparation of dilutions of tuberculin.

There are a large number of illustrations in the book, twenty-three being added in this edition. While many of them are very good, a few, such as the administration of oxygen by the funnel method, might be left out.

Altogether this is a good book and will be helpful to nurses and health visitors.

R. C.

THE RADIOLOGY OF PULMONARY TUBERCULOSIS.

—By J. E. Bannen, M.B., Ch.B., D.M.R.E. 1937. Baillière, Tindall and Cox, London. Pp. viii plus 156, with 39 figures in the text. Price, 12s. 6d.

THIS handy and copiously illustrated book deals mainly with x-ray diagnosis of pulmonary tuberculosis. After giving some details on the technique of chest radiography, the author proceeds to describe the radiological appearance of the normal lung, noting some anatomical and physiological points bearing on the subject. Here we would have liked to see included at least one radiogram of the normal chest, although the book is obviously meant for radiologists. The next four chapters deal with x-ray appearances, pathogenesis of pulmonary tuberculosis from the radiologist's point of view, and differential diagnosis, but the descriptions suffer from absence of references to the illustrations. Chapter VII is devoted to the clinical aspects of the disease and briefly describes different methods of examination for diagnosis. The book ends with a chapter on collapse therapy. The illustrations are clear and varied.

R. C.

PRENATAL AND POSTNATAL MANAGEMENT.—

By J. St. George Wilson, M.C., M.B., Ch.M., F.R.C.S., L.R.C.P., F.C.O.G. 1937. Edward Arnold and Company, London. Pp. viii plus 206. Illustrated. Price, 10s. 6d.

THIS short handbook provides a very practical introduction to the subject of prenatal and postnatal care. The information is very compressed and most of it is given in a rather dogmatic 'note' form rather than as a discussion of the subject.

The illustrations are many and most of them are good. But a diagram showing the vagina as a widely patent canal with a Dutch cap pessary in a position which is not generally accepted as the correct one is open to criticism.

The author makes some sweeping and pessimistic statements. He says that 'constipation is almost invariably associated with pregnancy' (page 3) and 'a time will come sooner or later when she will need aperients' (page 35). This can hardly be said to be in accordance with experience in this country and suggests that insufficient attention is given to prenatal advice regarding diet and the intake of fluid. He also says that 'There is a certain amount of generalized adenoma (erosion) of the cervix in every married woman' (page 102) which suggests the impression gained in a hospital out-patient department rather than of an antenatal clinic.

The book is however a welcome addition to a much neglected subject and contains a great deal of very useful information.

M. I. N.

A TEXTBOOK OF OPHTHALMIC OPERATIONS.—By H. Grimsdale, M.B., F.R.C.S., and E. Brewerton, F.R.C.S. Third Edition. 1937. Baillière, Tindall and Cox, London. Pp. ix plus 322. Illustrated with 105 text-figures. Price, 17s. 6d.

THIS is the third edition of this excellent book which alone is sufficient evidence of its usefulness and success. It consists of twelve chapters and an index. The first chapter is devoted to operations on the eye muscles, the second to operations for ptosis, the third and fourth to operations on the lids, the fifth to operations on the conjunctiva, the sixth is on enucleation and its substitutes, the seventh is devoted to operations on the lachrymal apparatus and bones of the orbit, the eighth is on cataract, the ninth on after treatment of cataract, the tenth on the operative treatment of glaucoma, the eleventh on some operations on the cornea, sclerotic and iris, and finally the twelfth is on foreign bodies in the eye.

In the present edition historical operations and those of interest in the development of operative surgery have been largely eliminated, but there are still many obsolete operations that could with advantage be left out, more especially those pertaining to the lids.

The chapters on glaucoma and cataract are especially good. Ophthalmic surgeons working in India would however hardly agree with the authors' remarks that more than half the operations of 'couching for cataract' would be considered successful, or that an operation for depression or reclinication of a cataractous lens should be attempted by any one other than a quack.

Many eye surgeons would also differ with the authors that posterior sclerotomy is a scientific operation for the relief of acute glaucoma, even as a temporary measure. It should be classed as a desperate operation for a desperate condition of the eye. There is no anterior chamber, no matter how shallow, that cannot be entered with a fine knife.

On the whole the book is an excellent one, well provided with illustrations which very rightly are largely diagrammatic. It is written in simple and clear style and is eminently practical. At the end of each chapter is a list of authorities to which the reader can refer for more detail.

We recommend it as a most useful addition to the library of every medical man connected with eye work in India.

E. O'G. K.

PHARMACOPŒIA OF THE GOVERNMENT OPHTHALMIC HOSPITAL, MADRAS. Pp. 37. Price, As. 14 and **ROUTINE METHODS OF TREATMENT IN THE GOVERNMENT OPHTHALMIC HOSPITAL, MADRAS.** Pp. 33. Price, Re. 1. By Lieut.-Colonel R. E. Wright, C.I.E., M.D., D.P.H., I.M.S., and Rao Bahadur K. Koman Nayar, L.R.C.P. & S., D.O.M.S. 1937. Printed by the Superintendent, Government Press, Madras

THESE two excellent little books compile the routine methods of treatment in the famous Government Ophthalmic Hospital, Madras.

The pharmacopœia contains the various drops, injections, lotions, oils, ointments, pigments, powders, mixtures, etc. The booklet, *Routine Methods of Treatment*, contains, amongst the most important articles on anti-syphilitic treatment, the treatment of arterial spasm and ischæmia, the treatment of collapse under anaesthesia or narcosis, the various uses of electrolysis, the various pre-operative and post-operative hæmostatics, hypnotics and sedatives, the treatment of hookworm, malaria and leprosy, general narcosis and the treatment of respiratory failure, the non-operative methods of treatment of primary glaucoma, the prophylactic and curative serum treatment for diphtheria and tetanus, the treatment of sympathetic ophthalmia and trachoma, tattooing of the cornea, etc.

We have nothing but praise for these two publications which are simply written, explicit and practical. The authors are to be congratulated on giving the

benefits of their experience in such a concise, practical way to medical men working in India.

Both booklets are cheap and we venture to say that no medical man who has to attend eye patients should be without them. We sincerely hope that they will be brought to the notice of the medical profession.

E. O'G. K.

DISEASES OF THE NOSE, THROAT AND EAR: A HANDBOOK FOR STUDENTS AND PRACTITIONERS. By I. Simson Hall, M.B., Ch.B., F.R.C.P.E., F.R.C.S.E. 1937. E. and S. Livingstone, Edinburgh. Pp. xv plus 423. Illustrated. Obtainable from Messrs. Butterworth and Company (India), Limited (Publishers), Calcutta. Price, Rs. 7.

THIS is yet another book designed for the needs of the busy practitioner and the student. It is strictly limited to this aim.

No attempt has been made to describe in elaborate detail diseases of the ear, nose and throat which the student and practitioner for lack of training and experience might fail to recognize. For this reason there are many omissions, but this is more than balanced by a fuller discussion of commoner complaints. The best chapter in the book is the one on the larynx which finishes up with a description of 'endoscopy' in quite sufficient detail to let the practitioner know what can be achieved by this method. A warning is also given that in unskilled hands it may be so dangerous as to endanger life. In fact, it is a highly specialized branch and may be called a speciality within a speciality.

Tracheotomy is given the full description which it deserves and there is a paragraph on 'detubation' which is overlooked in so many books nowadays.

There is a very useful appendix which consists of instructions for the preparation of ear, nose and throat cases for operation, instructions as to how to use head radiant-heat baths and ends with a short list of useful prescriptions.

Altogether an admirable little book which fulfils the author's intentions.

H. E. C.

A MANUAL OF PRACTICAL TROPICAL SANITATION.—By J. Balfour Kirk, M.B., Ch.B., M.R.C.P., D.P.H., D.T.M. & H. 1937. Ballière, Tindall and Cox, London. Pp. ix plus 300, with 46 figures.

DR. BALFOUR KIRK'S is a welcome addition to the small group of elementary books on public health in tropical countries. The subject-matter of this book is much more extensive than the title would suggest. It is, in fact, a small treatise on general hygiene. There is hardly any branch of human knowledge which may not be applied for the benefit of personal and communal health, and it has been the endeavour of the modern public health worker to employ as much as possible of the vast knowledge which the phenomenal expansion of scientific research has placed at their disposal.

To select suitable material for use by non-medical practical sanitarians and present it in a simple, concise, and readily-assimilable form is no mean task. It may be at once said that in this Dr. Kirk has succeeded very well. However, much of the matter contained in the first two chapters could have been omitted from a book on practical sanitation.

Communicable diseases loom large in the programme of public health workers in the tropics. Nearly half of the book is devoted to this section and to disinfection, but even so, only a very sketchy description of each disease has been possible. The opening pages of chapter 3 give much useful information to a layman concerning epidemiology. A little more expansion of this portion to include some information on immunity and the explanation of such terms as 'incubation period' would be desirable.

In a small book like this it is naturally difficult to keep a proper balance in the treatment of the various

subjects, and one does come across some portions which occupy more space than they deserve. The paragraph on standardization of disinfectants may be cited as an illustration. A note on balanced diet could have been added with advantage. The last chapter contains very useful data to facilitate calculations usually made by health workers. This small book will be found of great interest and utility by a large number of people interested in public health work in the tropics.

CHEMICAL PROCEDURES FOR CLINICAL LABORATORIES.—By M. R. Mattloe, A.B., Sc.W. 1936. Henry Kimpton, London. Pp. 520. Illustrated with 90 engravings and 2 coloured plates. Price, 30s.

THE physician is daily becoming more dependent on chemical procedures for the correct diagnosis of their diseases and the treatment of his patients. There are many books on laboratory technique, but not so many that are devoted entirely to chemical procedures. The book under review is a very good example of a guide to the more practical and useful methods with which the 'compleat physician' should be familiar, so that, even if he has not time to carry out the examinations himself, he can do so with the help of an unqualified technician.

There are four parts, on the blood, urine, gastrointestinal secretions, and miscellaneous biological fluids, respectively, and finally there is an appendix. Whilst as regards length the four parts are arranged in *diminuendo*, as regards their appeal to the reviewer they are arranged in *crescendo*, and in this is included the appendix. The chapter on gastric analyses is good and contains some useful type acid curves. The gruel test meal seems to be favoured, as it is in Great Britain but not usually in America. The table showing the types of curves found in different diseases is one that is copied from textbook to textbook, and it is surprising that one based on larger figures could not be found. Surely most laboratories could give data for gastric analyses on more than seven cases of gall-stones?

The appendix contains a number of useful sections, not the least being that on the statistical treatment of data. This contains formulae with sufficient explanation to help those with even the rudiments of mathematical knowledge. We feel sure that the advanced statistician, the arch enemy of the practical laboratory worker, would not approve of this section: even the reviewer had some doubts about the simplified formula given for obtaining the 'probable error', nevertheless, it is a valuable addition to the book. We can recommend this work strongly to the physician, the student, and the laboratory worker.

CLINICAL LABORATORY DIAGNOSIS.—By S. A. Levinson, M.S., M.D., and R. P. MacFate, Ch.E., M.S. 1937. Henry Kimpton, London. Pp. 877. Illustrated with 144 engravings and 13 plates. Price, 45s.

THIS book was a very ambitious undertaking; the authors have attempted to provide in one volume the technique and rationale of all laboratory diagnostic procedures, cytological, histological, chemical, bacteriological, protozoological and helminthological, combined with enough anatomy, physiology and clinical medicine to make the subject intelligible to the student who has not learnt his clinical medicine and to the physician who has forgotten his physiology and anatomy. To say that the attempt had been an unqualified success would necessitate a combination of generosity and elasticity of conscience in a reviewer which should disqualify him for the work he had undertaken: on the other hand to call it a dismal failure would be not only a churlish and ungenerous return for the very hard work that the authors have put into the book, but frankly untrue. In other words the book has some outstanding qualities, but many faults. If the book goes into another edition, which we sincerely hope it will, we also hope that the authors will spend as much energy in correcting

its mistakes and purging it of its redundancies as they did over the original compilation.

Amongst the redundancies are some long quite useless lists and tables; for example, we cannot really see what useful purpose the list of 'Common infectious diseases and the causative organism' serves. One reads, '*Amoebiasis*. Infections caused by amoebae'. '*Ankylostomiasis*. Infection with *Ankylostoma duodenale*'. One's interest gradually works up, after a slight set-back in finding asthma included as an infectious disease, until it reaches almost white heat when one finds that filariasis is caused by *Filaria bancrofti* and Leishmaniasis by (no, you are wrong, there is a catch here) *Herpetomonas donovani*. We feel they have rather cheated over '*Rabies* caused by a specific filterable virus', and they have certainly slipped up over '*Rat-bite Fever*. *Leptospira icterohæmorrhagiae*'.

They claim to describe the technique of spleen puncture, which they say is a useful method of distinguishing Gaucher's from Niemann-Pick's disease, but had they said 'You just puncture—the spleen' they would have gained half a page and the reader would have lost nothing. The only point they emphasize is that, as the syringe is withdrawn, suction should be maintained, which is the exact reverse of the reviewer's experience.

On the credit side, there is an immense amount of information that is available in no other book and, as much of this is taken from unpublished records, it is probably available nowhere else. This includes hæmatological data for children of various ages from birth to puberty. There is even a graph showing the differences in the normal sternum puncture findings in children of different ages; from 1 to 3 years the myeloid/erythroblast ratio is 2 to 1, whereas at 10 years it is 3½ to 1 which is about the adult proportion.

The section on gastric analysis has been done very thoroughly, many different types of acid curve are given, and the difference between the normal curves after the gruel meal and the alcohol meal, respectively, is brought out very clearly, again in a way that will be found in no other book that we know.

We will conclude by saying that the book is a unique source of information on many subjects and will be a very valuable addition to any medical library. A well-equipped clinical laboratory can scarcely afford to be without a copy.

L. E. N.

CLINICAL CHEMISTRY IN PRACTICAL MEDICINE.

—C. P. Stewart, M.Sc. (Dunelm.), Ph.D. (Edln.), and D. M. Dunlop, B.A. (Oxon.), M.D., F.R.C.P.E. Second Edition. 1937. E. and S. Livingstone, Edinburgh. Pp. lx plus 372. Illustrated. Obtainable from Messrs. Butterworth and Company (India), Limited, Calcutta. Price, Rs. 7

THE book has been written from the point of view of imparting the broad general knowledge of biochemistry to the general practitioner as is essential to his every-day practice. It cannot be considered either as a standard textbook or as one suitable for laboratory workers. The main utility of the book lies in the fact that it deals with such simple, useful and at the same time reliable methods of laboratory analysis as are essential to the busy practitioner in making a quick diagnosis in order to find out a correct line of treatment for his patient.

The importance of a broad general knowledge as to how the various biochemical analyses are carried out and a more detailed knowledge of the actual methods of carrying them out (for example, important clinical tests of blood, urine, sputum, etc., which do not require much time and equipment and which can easily be performed in the practitioner's own surgery) are essential to every practitioner of medicine, surgery and gynaecology. This book will be a great help to keep him up to date and would be of great value in making a quick diagnosis in cases of emergency instead of having to wait until the report comes from the laboratory.

The book has been well written and the author has been successful not only in describing, within a small compass, the biochemical investigations of the more important every-day problems but also in explaining the rational foundation on which such tests rest, the idea being that such explanation is of help in understanding the mechanism of many of the pathological processes concerned.

J. P. B.

AN INTRODUCTION TO BACTERIOLOGICAL CHEMISTRY.—By C. G. Anderson, Ph.D. (Birm.), D.Bot. (Lond.). 1938. E. and S. Livingstone, Edinburgh. Pp. viii plus 278. Illustrated. Obtainable from Messrs. Butterworth and Company (India), Limited, Calcutta. Price, Rs. 7

THIS handy volume is divided into three parts. The first part deals with general considerations, such as hydrogen-ion concentration and pH, oxidation-reduction potentials, colloids and adsorption, enzymes, and the chemical composition of bacteria, yeasts and lower fungi. The second part deals with metabolism and discusses the nutrition of bacteria, the adaptive and constitutive enzymes, growth factors, bacterial respiration, nitrogen and carbohydrate metabolism, alcoholic fermentation, the fermentation products of lower fungi, industrial fermentations for the production of alcohol, glycerol, acetone, lactic acid, power-gas, citric acid, etc., and finally the proteins, polysaccharides, lipoids and pigments of micro-organisms. The third part discusses some aspects of immunochemistry such as antigens, haptens, antibodies and complements and the mechanism of antigen-antibody reaction. An appendix at the end gives a concise description of the methods used in isolating and identifying the different chemical products of bacterial metabolism. There are also references to original literature at the end of each chapter to help the reader to study details.

Our knowledge of the chemistry of bacterial metabolism has grown very rapidly during the last 10 or 15 years and there seems to be no single book giving a survey of the recent progress of the whole field of bacteriological chemistry in a convenient form. The author has discussed this highly-technical subject in a very clear and readable form and the volume will be welcome not only to students going up for honours, diplomas or degrees in bacteriology but also to the wider circle of bacteriologists, medical men and people interested in the recent advances in biochemistry.

S. G.

MANUAL OF CLINICAL AND LABORATORY TECHNIC.—By H. B. Weiss, A.B., M.D., F.A.C.P., and R. Isaacs, A.M., M.D., F.A.C.P. Fifth Edition. W. B. Saunders Company, Philadelphia and London. Pp. 141. Price, 6s. 6d.

THERE are a large number of books dealing with laboratory technique, but there are very few of such a small size and yet covering so much ground as the present volume.

The descriptions given in most of the sections, though short and concise, contain almost all the necessary information about the ordinary routine laboratory work, but the chapters on history-taking, physical examinations and the laboratory report form, in the beginning of the book, and the last chapter, on the nutritional value of food, are far too elaborate and not of much use; the space saved might have been utilized to extend the section on blood examination which is too abbreviated and could be improved upon.

The claim made by the authors that it provides an available source of some of the newer tests is justified. On the whole, the manual provides, as observed by the authors, 'a ready reference to the gross details of the most common laboratory tests'. It should be useful to the laboratory workers on account of its small size and cost, and for the very useful information that it contains.

C. R. D. G.

AN INTRODUCTION TO PHYSICAL ANTHROPOLOGY.—By E. P. Stibbe, F.R.C.S. Second Edition. 1938. Edward Arnold and Company, London. Pp. vii plus 230. Illustrated. Price, 10s. 6d. Obtainable from Messrs. Longmans Green and Company, New York

THIS is the second edition of the little book which well deserves its title. A new feature of this edition will be seen at the end in the appendix in the statistical data by Dr. W. A. Smart. If this, as has been remarked in the preface, is intended to guide 'the man actually working in the field' we have our doubts about the advisability of its inclusion in a work chiefly designed as an introductory lesson for the amateur and the student, who are less likely to relish the underlying mathematics.

The main subject-matter of this book has, however, been presented in good sequence and the author has succeeded while carrying his readers, step by step, through the different phases of his study in creating a deep interest in the subject.

If the criterion of successful book writing be the ease with which the reader is able to grasp the subject when he closes the book, it is abundantly manifest that Mr. Stibbe has been remarkably successful. The writing is clear, comprehensive and uniformly interesting, and is conspicuous by the absence of any confusing details to embarrass a beginner.

We should have been happier, however, to find the technical names used in chapter XII, explained either in the previous section XI, or mentioned in the glossary at the end. A beginner, who has learnt in the classification of the skull according to the length-breadth index or height index, as mentioned in the chapter (XI), is likely to wonder when confronted with other terms used in the subsequent section XII, *e.g.*, mesati-cephalic, akro-cephalic, tapeino-cephalic, etc., which are nowhere mentioned or explained.

Though the book is intended for students of anthropology we feel sure that students of human anatomy will profit by it as well.

In the matter of printing, a more careful proof-reading would have eliminated such minor faults as will be seen on page 18, para. (c), namely, 'wit' for 'with'. The illustrations are uniformly good and neat, the get-up of the book attractive, and on the whole the publisher's task is satisfactory.

THE DISSECTION AND STUDY OF THE SHEEP'S BRAIN AS AN INTRODUCTION TO THE STUDY OF THE HUMAN BRAIN.—By John Wilkie, B.Sc. 1937. Oxford University Press, London. Humphrey Milford. Pp. xv plus 95. Illustrated. Price, 6s. Obtainable from Oxford University Press, Bombay and Calcutta

THIS is a short treatise on the sheep's brain, and is intended to be complementary to the dissection of a human brain; and where such materials may not be sufficiently available also to supplement it.

Indeed, the human brain offers a very complicated structure for study; especially so are those parts that have undergone remarkable evolutionary transformations, *e.g.*, the rhinencephalon and flocculus, para-flocculus, etc., in the cerebellum; but these however are well developed and easily discernible in the brain of a lower animal.

A preliminary study of the brain of a macrosmatic mammal cannot but help to minimize the difficulties met with in the dissection of a complex human brain; besides, it enables the student to grasp the fundamental changes involved and compare those with the corresponding human parts.

Mr. Wilkie's book is therefore very welcome and is sure to fill a very distinct need.

The plan of the book is commendable from the practical point of view. After the first dissection is over the student has made a general survey of the brain as a whole and is led to the details of the deeper structures in the second dissection. The hand sections made at the different levels offer material for a profitable study and application of the knowledge gained in the previous dissections.

We have little doubt that Mr. Wilkie's work will help the student of human anatomy to set his knowledge on a background of comparative anatomy, as it will help the general students of zoology to grasp the nature of evolutionary changes undergone in the human brain.

We recommend the book to every student as a guide during his dissection of the 'brain'.

S. C. S.

PRACTICAL NEURO-ANATOMY: A TEXTBOOK AND GUIDE FOR THE STUDY OF THE FORM AND STRUCTURE OF THE NERVOUS SYSTEM.—By J. H. Globus, B.S., M.D. 1937. Baillière, Tindall and Cox, London. Pp. xxii plus 387, with 92 figures in the text and 55 plates. Price, 27s.

THE most difficult branch of anatomy is undoubtedly the anatomy of the nervous system. A book in which the practical side of this subject is clearly and accurately portrayed is naturally very desirable in view of the great advances that have been made within recent years in the surgery of the nervous system.

An introduction of nine pages contains a brief description of the embryology of the brain and spinal cord. As the development of the nervous system is an important approach to the study of brain tumours and therefore has a great practical bearing, this section is too brief. If the book was purely practical one would not make this comment, but it is full of detailed description.

Directions are given for the dissection of the brain, cerebellum and the spinal cord. The text is most lucid and comprehensive and the illustrations both in the embryological and the general section are excellent. There are 256 pages of close reading.

A description is given at the end of the anatomical section of methods used in the preparation of nervous tissue for the study of its microscopic structure.

This section is followed by plates which are perforated in such a way that they may be detached. On these are inserted semi-completed drawings so that the student may add the desired detail and build up the component parts of the nervous system from the diagrams in the main part of the book. Directions are given to replace these diagrams by means of gummed paper after completion.

The book contains anatomical, histological and physiological details which cannot possibly be studied in any practical sense. The title of the book is therefore rather a misnomer. The book is both practical and theoretical but too descriptive for any practical textbook. It is impossible to identify tracts by any study of the gross anatomy of the brain. It would be preferable if the book were divided into two sections, one theoretical and the other practical.

It can be regarded as a textbook on the anatomy of the nervous system and as such is one of the best available. Such textbooks are, as a rule, very brief and there are but few in the English language.

T. H. T.

THE DEVELOPMENT OF THE VERTEBRATE SKULL.—By G. R. deBeer, M.A., D.Sc., F.L.S., F.Z.S. 1937. Clarendon Press, Oxford. Pp. xxiii plus 552. Illustrated with 143 plates. Obtainable from Oxford University Press, Bombay and Calcutta. Price, 30s.

THE skull has been studied by all those interested in comparative anatomy, anthropology and palaeontology; much, therefore, is known already. Prof. deBeer's special studies, carried out over a period of 15 years, and done systematically and with a definite object in view, have brought forward many interesting conclusions, and have moreover revealed what still remains to be explained, and to what extent and in what directions such works should be continued.

The book is an embodiment, not merely of facts gathered from systematic studies on the construction of the vertebrate skull, but also of data obtained from experiments on its morphogenesis. The book is not intended to be a textbook, but is designed to serve a special purpose, that of a reference book for special

APRIL, 1938]

studies on the skull and also for information regarding its phylogenetic history and morphology.

To encompass the overwhelming mass available on the subject is a stupendous task in itself, but to compile this material on a uniform morphological basis, using uniform nomenclature throughout, to enable a conducive comparative study, and that with precision, clearness and devoid of any redundancy, becomes a task of a very high standard indeed. This we feel has been done in a masterly way by Prof. deBeer.

The scheme of the work is well planned, and consists of four sections: The introductory section dealing with the historical aspects, and the nature of tissues forming the subject matter of the study; (2) the systematic section, dealing with the various groups of vertebrates with a detailed description of a type of each group. The other two sections, (3) comparative and (4) general, provide information regarding the morphological units of the different groups for comparison and to trace the phylogenetic history.

In subsections 38 and 39 is given the experimental evidence of the development of cranial cartilages and bones, and, in the appendix at the end, the various points on which further work is required have been given. A very complete, comprehensive and well-arranged bibliography has been incorporated.

The plates are explanatory to the context and are uniformly satisfactory.

In writing the book, the author was aware of the danger of overgrowth and we are confident that the arrangement of dealing with each subject in a comprehensive section, making reference to other sections unnecessary, was the best solution.

While, therefore, the book is scarcely intended to be read from cover to cover, we, nevertheless, hope that it will have a wide application in providing interesting and profitable reading for those interested in comparative anatomy and anthropology, and also for general students of biology and research workers—each class having his subjects in appropriate section or sections.

The publishers deserve sincere congratulations upon their excellent achievements.

S. C. S.

MEDICO-LEGAL ASPECTS OF THE RUXTON CASE.—By John Glaister, M.D., D.Sc., Barrister-at-Law, and J. C. Brash, M.A., M.D., F.R.C.S. Ed. 1937. E. and S. Livingstone, Edinburgh. Pp. xvi plus 284, with 172 illustrations. Price, Rs. 14. Obtainable from Messrs. Butterworth and Company (India), Limited, Calcutta

On the evening of 14th September, 1935, in Lancaster, Dr. Buck Ruxton murdered his wife and housemaid. He disposed of their bodies piecemeal in various ways. A large proportion of the two bodies was found in small pieces, in a ravine in Scotland some hundred miles away. A few other pieces were found in the vicinity. These pieces were collected, preserved and photographed. Although most of the identification marks were cleverly removed from these bodies, their identity was proved beyond any doubt. The proof that these pieces were in fact the remains of Mrs. Ruxton and the housemaid was an important link in the chain of evidence on which Dr. Ruxton was eventually convicted and hanged.

The book under review gives the whole story of how these remains were pieced together. It is the record of a clever piece of combined anatomical, anthropological, and medico-legal work, of which the authors are apparently, and from a scientific point of view very justifiably, proud.

The very existence of this book is a terrible indictment of the present extremely complicated state of the structure of human society. Medical science has become so intricate that the expenditure of hundreds of pounds and much of the valuable time of a number of scientific workers are sometimes necessary to prolong a life, but this is nothing compared with the amount of scientific labour and the thousands of pounds that must have been expended to cut short the life of the prisoner in this case. One cannot help wondering whether swift

justice with its occasional miscarriages was not perhaps better in the long run, as miscarriages still occur.

The book is extremely interesting reading from many points of view; we can strongly recommend it for its scientific value, for anyone who enjoys 'thrillers', and finally for intending murderers who will either be able to profit by Dr. Ruxton's mistakes, or, better still, take warning from his failure to destroy all traces of the identity of the victims, and, we hope, reconsider their decision to resort to violent crime.

The publishers have done their work excellently and have produced a book that is worthy of a much pleasanter subject.

L. E. N.

LEHRBUCH DER BIOLOGISCHEN HEILMITTEL.—By Dr. Med. Gerhard Madaus. Abteilung 1: Heilpflanzen. Volumes I, II and III. 1938. George Thieme, Verlag, Leipzig. Vol. I:—Pp. xxiv plus 902. Illustrated. Volume II:—Pp. from 903 to 1884. Illustrated. Volume III:—Pp. from 1885 to 2864. Illustrated. Index volume pp. 144. Price, R. M. 95

THE first volume discusses the genesis and foundation of biological therapeutics, homœopathy in biological therapeutics, healing with herbs, relation between plant and soil, cultivation of plants, important constituents of plants such as vitamins, hormones, enzymes, alkaloids, glucosides, saponins, colouring matters, tannins, essential oils, resins, fats, proteins, amino acids, etc. The special section dealing with individual plants has also been begun in this volume. Under each plant is given the name, source, distribution as shown on a map, a good photograph of the plant either coloured or otherwise, a short botanical description, a general and historical description, the medicinal action, use in practice, parts used, ordinary and homœopathic doses, and finally some recipes. The references to the literature from which the information has been collected are given in small print at the end under each plant. Eighty-nine plants have thus been discussed in vol. I, 174 plants in vol. II, and 190 plants in vol. III. The General Register gives an index of the Latin names of the plants or drugs, an index of the German names of plants, an index of the chemical constituents, and finally an index of the therapeutic uses.

The author has to be congratulated for the collection of such a large mass of useful knowledge in these volumes, which will prove helpful not only to botanists, agriculturists and medical men, but also to other workers who desire to develop the resources of the medicinal plants in their own country.

ESSENTIALS OF MEDICINE: A TEXTBOOK OF MEDICINE FOR STUDENTS BEGINNING A MEDICAL COURSE, FOR NURSES, AND FOR ALL OTHERS INTERESTED IN THE CARE OF THE SICK.—By C. P. Emerson, M.D., and N. G. Brown, R.N. Twelfth Edition. 1936. J. B. Lippincott Company, Philadelphia and London. Pp. xxi plus 608. Illustrated. Price, 12s. 6d. Obtainable from Messrs. Butterworth and Company (India), Limited, Calcutta. Price, Rs. 9-6-0

THIS small handbook should prove useful to probationers and nurses, to help them to take an intelligent interest in their work.

THE BUSINESS SIDE OF MEDICAL PRACTICE.—By T. Wiprud. 1937. W. B. Saunders Company, Philadelphia and London. Pp. 177. Illustrated. Price, 12s.

THIS is a useful guide to the practitioner. It contains many valuable suggestions that will apply equally to practice in this country, but is, of course, written mainly for the practitioner in the United States of America.

OTHER BOOKS RECEIVED

State Insurance and Panel Practice for India. By Dr. C. P. Chaube. The Hindustan Times Press, New Delhi. Pp. 228. Price Rs. 2.

Abstracts from Reports

ABSTRACT OF THE ANNUAL REPORT FOR 1935 OF THE PUBLIC HEALTH COMMISSIONER WITH THE GOVERNMENT OF INDIA

(Continued from last issue, p. 189)

FEVERS

Mortality under the general heading of 'Fevers' diminished as compared with the previous year by 202,326. This is described as a small decrease and is not greater than might occur by chance. An interesting fact is that 73 per cent of all the deaths from fevers were recorded in the northern areas stretching from Bengal to the North-West Frontier Province.

MALARIA AND QUININE

About 44 per cent of the total fever deaths are said to be due to malaria. The accuracy of these figures is discussed, and the view given is that the recorded total is exaggerated and that the actual truth lies somewhere round one and a quarter million deaths. Even at this lower level the figure can only be described as appalling. Malaria, causing as it does immeasurable misery and acting as a powerful deterrent to economic progress, constitutes one of the most formidable problems with which the Governments in India are faced.

Of the anti-malaria measures carried out in the different provinces, measures for the prevention and destruction of mosquitoes were practically all of a temporary nature. In these circumstances quinine had to be relied on largely for the amelioration of outbreaks. It is not suggested that quinine will eradicate malaria, but it certainly reduces the deaths, lessens the duration of the illness and prevents a considerable proportion of relapses. The annual consumption of quinine in India is stated to be only about 200,000 pounds. With what seems sound reasoning, the report states that India's annual requirements, if every sufferer were treated efficiently, should be in the neighbourhood of 1,250,000 pounds. These two figures are enough to indicate the vast shortage of this valuable drug.

Efforts at increasing the popularity of quinine are stated to have been made by the Central and Provincial Governments at different times, but at no time have these attempts been particularly successful. The greatest difficulty has been to place the drug at the disposal of the villager at a price which he can afford to pay. Propaganda to popularize the use of the drug must largely fail if the advertised drug remains, as it is now, beyond the average villager's financial resources.

ENTERIC FEVER

It seems clear that the recorded statistics of enteric fever are a gross underestimate of its prevalence. As the diagnosis of the disease is often dependent on accurate bacteriological examination, many enteric infections are probably missed. During the year under review a severe epidemic in Delhi city caused no less than 588 deaths, and until the existing insanitary conditions in that city are abolished, it is likely that similar figures will continue to be returned.

TUBERCULOSIS

Some of the most interesting pages of the report are devoted to the important subject of tuberculosis. The disease, particularly in its pulmonary form, has markedly increased during the last three decades, especially in the large urban and industrial areas. Only within recent years, however, has the infection begun to spread to villages, this extension of infection being partly due to the return of infected industrial workers to their homes and partly to the great development of road transport.

Regarding the vulnerability of India's rural population to tuberculosis, the report contains the following important statement:—

'Once infection is introduced into the rural villages, it is almost certain to spread rapidly and to cause a heavy morbidity and mortality. This fact has recently been illustrated in striking degree. The Gurkhas who

come from the remote state of Nepal show, in comparison with other men of the Indian army, a much higher susceptibility to and mortality from tuberculosis. These gallant little soldiers, in other words, are from the tubercularization point of view members of a primitive race and being completely non-immunized are unable to resist an infection which often proves rapidly fatal. This is to a large extent the position of the great mass of the rural populations of India at the present time and as there are ominous signs that infection is spreading to and through these rural areas, the time has come when preventive campaigns should be extended to include these areas'.

Little accurate information is at present available regarding the extent of the disease. Investigations have shown that in 50 per cent of the cases there is a history of contact with another case in the family. Although India has not yet planned a national campaign against tuberculosis, there is in existence a number of tuberculosis associations in various parts of the country. The funds of these associations are limited, and in order to meet the situation much larger financial resources are essential and a large number of specially trained medical officers, nurses and home visitors are required. The object should be to have at least one special tuberculosis clinic in every municipality and rural town where skilled treatment and advice would be available to all. Once these clinics are established, it will be possible to arrive at a more accurate estimate of the incidence of the disease and of the needs of the sufferers. The work of the clinics will also indicate the extent to which hospital and sanatoria beds are required. It will never perhaps be possible to provide a sufficient number of beds to accommodate the hundreds of thousands of tuberculosis patients in the country, but this should not deter those interested in the prevention of the disease, because other methods can be successfully practised. The report while not denying that additional hospitals and other beds are necessary, points out that these are by no means the first requirements of an anti-tuberculosis campaign.

LEPROSY

Leprosy is most commonly met with in certain parts of Southern and Eastern India, where as many as 2 to 3 per cent of the population may be infected and where the incidence in groups of villages may be 5 to 7 per cent or even higher. In certain of the Himalayan valleys leprosy is also very common: in Central India, its incidence is lower and in the North-West lower still. The suggestion has been made that these variations may have some association with dietary conditions, since the virile races of the North-West, who ordinarily use a well-balanced diet, show less leprosy than the less virile races of the South and East whose diet is relatively poor. But other factors cannot be left out of consideration. For instance, it has been noted that a dry climate, hot in summer and cold in winter, is associated in India with a low leprosy incidence. Such areas, however, coincide to a greater or less extent with those inhabited by the more virile and well-nourished races. The disease is, again, frequently associated with bad social and hygienic conditions and poverty, although these conditions are not always present. Our knowledge of the epidemiology of leprosy is therefore incomplete and further investigations are necessary.

Many of the cases seen are of a relatively mild neural or neuro-macular type in which the disease does not progress to the more severe forms. These mild types are regarded by most workers as non-infectious. Of the estimated total of one million cases of leprosy in India, probably about 350,000 are a public danger. Isolation of infectious cases is known to be a most useful preventive measure, but the lack of a public opinion, quite apart from limited financial resources, makes it impossible to legislate for compulsory isolation. The existing Lepers Act provides for the compulsory removal of indigent lepers to institutions and it contains provisions for the prevention of lepers following certain occupations; yet, for different reasons, most of the provisions of this Act have been found difficult to apply.

The only agency working on an all-India basis is the Indian Council of the British Empire Leprosy Relief Association which now has branches in most provinces. The Council maintains a leprosy research department, a training centre in Calcutta and a propaganda officer who tours all over India. Propaganda material is prepared in different languages and a quarterly journal in English is also published. Grants are made by the association to the provincial branches for leprosy work carried out in collaboration with or in addition to that done by provincial governments and local authorities. In addition to the activities of the provincial branches of the association, some provincial governments have their own anti-leprosy organizations which form a part of the activities of their public health departments. Leprosy surveys were carried out during 1935 in Bengal, the Central Provinces, Madras Presidency, the Punjab and the United Provinces. These indicated in general that the incidence of leprosy is higher than had been previously realized.

During the last ten years several hundred leprosy clinics have been established for diagnosis and treatment. It is usually impossible and often unnecessary to maintain a special staff for these clinics, and they are held in most cases in existing hospitals and dispensaries once or twice a week, at hours when other out-patients are not present. It seems reasonable that the treatment of leprosy should form part of the ordinary treatment of a hospital, provided steps are taken to exclude the spread of infection.

The leprosy asylums now in existence in India have accommodation for only about 10,000 cases. A few of these institutions are organized and staffed by Governments and local authorities, but most are maintained by Christian Missions with the aid of government grants. In recent years, efforts have been made towards the establishment of leper colonies where housing and food are assured to the leper, where conditions of life approximate to those of an ordinary village and where those who are able to work are employed in raising stocks of food for their own consumption, while regular treatment can be provided for the cure or early arrest of the disease. Concerning these colonies, the following remarks from one Provincial Director of Public Health are of interest:—

'A colony is much cheaper to establish and to maintain than an asylum. It has an advantage over clinics in that in the colony the treatment can be taken to the segregated lepers, instead of expecting the individual lepers to go for treatment to the nearest hospital clinic which is frequently some miles distant. Were sufficient colonies started throughout the province, they would exercise a marked effect in checking the spread of leprosy among the general population, and in addition they would exercise a marked effect on the control of pauper lepers. The class of leper who now leaves his village to go and beg in the towns would have a colony to go to, where his housing and food would be assured, where the conditions of life would approximate to those of his village and where he would get regular treatment leading to cure or early arrest of his condition. He would be spared the experience of being regarded as an outcast and having to descend to the level of a pauper.'

Special short post-graduate courses of instruction are of great value, and the Indian Council of the British Empire Leprosy Relief Association organizes a short annual course in diagnosis and treatment intended for doctors who are to be in charge of leprosy clinics. The instruction is given in the School of Tropical Medicine, Calcutta. In 1935, seventeen doctors from various parts of India attended this course and the total number trained up to date is 765. For doctors engaged in full-time anti-leprosy work longer periods of instruction are arranged.

Apparently, leprosy workers are becoming increasingly convinced of the importance of preventing infection amongst children. Epidemiological studies have shown that children and young people are much more susceptible than adults, and it is generally believed that serious infections are most frequently contracted in childhood.

Infections contracted in later life are said to produce milder and often non-infectious forms of the disease. The question of itinerant lepers is discussed in the report and figures are given of investigations made in Bengal regarding this class of patient. It has been found that only about 30 per cent of itinerant lepers are infective, and that the rest are burnt-out lepers would appear, therefore, that although control of the itinerant leper is desirable he constitutes rather an offence to aesthetics than serious danger to public health. The itinerant leper question would seem to form only a small part of the general problem of leprosy control.

CEREBRO-SPINAL FEVER

This disease would appear to be more prevalent than has been believed to be the case in the past. In Delhi city, there were 548 cases resulting in 216 deaths, which gives a case mortality of nearly 50 per cent. The figures given regarding cases admitted to the Campbell Medical Hospital in Calcutta show a case mortality of 61 per cent. The disease seems to have been most prevalent in the months of February and March whilst the highest incidence occurred among those between the ages of 15 and 44. The disease is undoubtedly associated with over-crowding.

MATERNITY AND CHILD WELFARE

While the figures recorded generally for maternal deaths are still far from accurate local investigations have revealed what must be regarded as a serious state of affairs. The report refers to the investigations in Assam carried out by Dr. Balfour, who found maternal death rates among the tea garden populations varying between 40 and 130 per thousand births. Enquiries in Madras Presidency in a number of municipal areas showed the rates to be three, four and sometimes five times as high as the English maternal mortality rate which has been the cause of great concern to the health authorities of England.

General information is lacking regarding the relative importance of the different pathological conditions giving rise to these maternal deaths, but some idea of the subject can be gathered from the records of certain women's hospitals which were summarized in the 'Journal of the Association of Medical Women in India' for August 1936. In that paper, 638 maternal deaths were analyzed and it was shown that sepsis (following delivery or abortion) accounted for 37.68 per cent of these. Next in order of frequency comes anaemia of pregnancy, accounting for 17.64 per cent. The large proportion of deaths due to sepsis is accounted for by the fact that many of the cases had been examined or mishandled and were infected before admission to hospital.

The following extract from the report gives a vivid idea of the magnitude of the problem facing the maternity and child welfare movement in India:—
'A total of 2,848,099 or 43 per cent of the deaths registered during 1935 occurred among children under the age of five years. Maternal deaths arising out of pregnancy are estimated to account for a further 150,000 to 180,000 deaths annually. Accurate figures, as already has been stated, are not available, but the maternal mortality rates for the larger towns indicate that large numbers of women die during the child-bearing age-periods. Along with this wastage of life a very serious wastage of health takes place. The percentage of women disabled as a result of pregnancy and labour may perhaps be taken as not less than 30 per cent and in a country where nearly ten million births are registered annually the percentage of women temporarily or permanently handicapped must be very large. To the physical disabilities from which both mothers and children suffer must be added loss of happiness and the neglect of temperament which follows in the wake of mother and her family. General environmental measures undoubtedly effect a reduction in the incidence of disease and mortality, but the extent to which limited in certain respects. Without doubt disease is limited in the use of the services provided must accompany

the establishment of these services if the maximum benefit is to be derived. Similarly the best midwifery schemes will be ineffective unless accompanied by widespread improvement in the general health¹.

An important factor in an efficient maternity service is ante-natal care of the mother. Much requires to be done in India in this connection. It is stated that many of the hospitals attached to medical colleges and medical schools and training institutions for midwives have inadequate arrangements, and the students leave college with a minimum knowledge of the scope and value of ante-natal work. This work should, of course, be an activity in every infant welfare centre, but progress is made difficult because few realize the importance of preventive work in this field.

In every province in India the number of maternity beds requires to be largely augmented. In the province of Bombay, which has supplied fairly complete returns, the beds work out at one to 1,102 confinements instead of one for every 100 confinements which is stated to be a reasonable, although not ideal, proportion.

Reference is made to the springing up of small maternity homes in many centres often as a result of voluntary enterprise. Many of these, however, are staffed by illiterate *dais* who are incapable of keeping records, or even of taking temperatures, and who have a very limited knowledge of asepsis and isolation. If the numbers of these homes increase in India, as there is every indication that they will, the question of their supervision should be taken up without avoidable delay by provincial authorities. The number of trained midwives available for midwifery work in the homes seems to be most inadequate. The employment of midwives by local authorities is not compulsory, but many municipalities and district boards have established domiciliary midwifery services. Madras Presidency would seem to be in advance of the other provinces in providing qualified midwives for work in the homes. The total number employed is 1,559, but even so as many as 50 per cent of all confinements are conducted by untrained attendants in that province.

Training schools for midwives are said to be quite insufficient for the needs of the country. Legislation regulating the training and registration of midwives has been passed in eight provinces, and it is hoped that in time the number of training schools will be increased and the standards of training improved. Apart from the scarcity of training schools and of trained midwives, a serious handicap exists in the lack of supervision of the midwives and their practice.

The account given of child welfare work is not encouraging. Approximately 800 infant welfare centres have been established, while some 60 medical women and 250 trained health visitors are employed in maternity and child welfare services now in existence in the country. Unfortunately, a considerable number of the centres are said to be badly organized, their work is uncoordinated, their records are not properly kept, and the information which is collected is not made available for future planning.

The account of the organization in the different provinces reveals a variety of methods of control. In some cases, the work comes under the public health department, while in others it is conducted altogether by voluntary societies. This transfer of responsibility and control from the public health department would seem unwise.

Particulars are given of the facilities for training health visitors. It should be explained that a health visitor is a qualified midwife who has taken an extra course of study to enable her to specialize in maternity and child welfare work. Schools for the training of health visitors exist in Bombay, Delhi, Lahore, Madras, Nagpur, Poona, and Rangoon, and schools are expected to open shortly in Calcutta and Lucknow. Most of these schools are at present maintained by voluntary associations. This is in keeping with the practice which was followed in England when the child welfare campaign was in its infancy. But with the growth of the movement, the governing authorities realized their responsibilities and took over the schemes, thus leaving the voluntary associations free for other pioneer work.

Provincial Governments in India may reasonably be expected at this stage to assume responsibility for the training of these health visitors.

PUBLIC HEALTH ADMINISTRATION AND ORGANIZATION

If Medical Officers of Health are to be of real value, they must be given some security of tenure. Experience in England showed that failure to provide such security was always a severe handicap to ordered advance in public health and India has already proved to be no exception in this respect. Instances could be quoted where health officers have been unable to retain their appointments for more than short periods because, as soon as they reported on glaring sanitary defects, vested interests represented on the municipal councils or local boards rendered their position intolerable. In order to prevent the development of such a situation, in other countries it has been found necessary to pass legislation making it illegal for municipal councils and local boards to dismiss an approved health officer without the sanction of Government. In a number of the provinces of India, local governments have already laid down this condition, so essential to progress, but the information supplied shows that, in other provinces, local authorities possess unfettered control over their officers.

The whole question of the organization and expansion of Public Health Departments is one deserving of serious notice from all interested in the health and welfare of this country.

HEALTH UNITS

A modern development in public health organization has been the establishment of health units. The idea of a health unit is to take a limited area and to staff it with adequate qualified public health personnel with the object of carrying out intensive work in different branches of preventive activity. This enables the administrator to gauge the response which is to be expected from the people. It also serves to demonstrate to Provincial Governments and to local bodies the progress which can be made if the question of public health is given the consideration, financial and otherwise, that it deserves. Further, if the work of the unit is successful, its accomplishments serve as an example to the population of the surrounding areas. The Rockefeller Foundation has been most generous in helping to establish these units, usually by defraying half the cost over a period of about five years. The scheme is well developed in the United Provinces. The health unit in Partabgarh has been in existence for some years and nine 'modified' health units have been set up. In Madras, a health unit was established at Poonamallee working over an area of 25 villages with a population of 42,000. In Burma, the Hlegu Rural Health Unit had another successful year. In addition to the benefits which they confer on the villagers, these units are very useful as field training centres for public health students.

HEALTH PROPAGANDA

A variety of health propaganda methods is reported from different provinces. Amongst the means adopted to capture the imagination of the people, with a view to enlisting their co-operation in the health measures designed for their benefit, are health exhibitions and health dramas, cinemas, broadcasts, lectures, magic lantern demonstrations, distribution of leaflets and posters and travelling cinema vans.

Particularly in recent years public health has become a matter of first-class interest to the editors of newspapers, and the daily and weekly press in India has usually given prominence to the notes on nutrition and other subjects which have issued in considerable numbers. Public health authorities are frequently asked for articles describing health activities or outlining certain schemes of public health improvement. The value of public health propaganda cannot be too strongly emphasized. The public must be got to realize that much of the ills from which they suffer can be prevented by improving their personal hygiene or the surroundings in which they live. In this way a public opinion will be created which will refuse to tolerate the unsatisfactory conditions which have been described in this report.

ADULTERATION OF FOOD

Figures are given from the different provinces showing the number of food examinations carried out and the percentage of foodstuffs found adulterated. These reveal a state of affairs which seems to require drastic action. For example, the percentages of ghee samples found adulterated in the different provinces were as follows:—North-West Frontier Province, 41 per cent; Punjab, 45 per cent; United Provinces, 15 per cent; Bihar and Orissa, 58 per cent; Bengal, 45 per cent; and Assam, 52 per cent. The corresponding percentages for adulterated milk samples were North-West Frontier Province, 64 per cent; Punjab, 60 per cent; United Provinces, 7 per cent; Bihar and Orissa, 59 per cent; Bengal, 66 per cent; and Assam, 43 per cent.

Food Adulteration Acts are in force in a number of provinces but, whatever be the reason, these seem to be largely ineffective in protecting the public against fraudulent and dangerous substitutes in the food which they purchase. Administration of the Acts is in the hands of the local bodies, and it is not difficult to imagine that the vested interests of dishonest food merchants constitute an obstacle to their efficient working. The matter is one which requires to be thoroughly explored and it is understood that, as in the case of maternal and infantile mortality, an *ad hoc* committee is being set up under the Central Advisory Board of Health to report on the whole question of adulteration of food in India, and to make recommendations for stopping what seems a public scandal, if one is to judge by the figures given in the report.

INTERNATIONAL HEALTH ORGANIZATIONS

An account is given of the activities of a number of International Health Organizations and Conferences on which India was represented during 1935. The first of these is the Office International d'Hygiene Publique, Paris, which meets each year in May and October. The problems dealt with seem to cover a wide sphere. Among the subjects were international quarantine, sanitary provisions in the control of aerial navigation, and measures for the prevention of the spread of yellow fever. India is critically concerned with subjects such as these, and, from the account given, it would seem that India's interests were efficiently protected in the decisions arrived at.

The danger of the introduction of yellow fever into India has been a subject of concern to its public health authorities for many years. With the development of air traffic, the question has become one of urgent importance. During more recent times, the Government of India's representative at the meetings of the Office International d'Hygiene Publique has unfailingly impressed on his fellow delegates the grave view which his Government take of the potential danger, and the Government of India's attitude has been abundantly justified by recent events. In the first place, a new air route has come into operation between Lagos and Khartoum where it links up with the Capetown-Cairo route. There is therefore the possibility of infected persons and mosquitoes being carried from endemically infected areas in West and Central Africa to India within the incubation period of the disease. The recent discoveries of yellow fever research workers are calculated to give further cause for alarm. A new variety of yellow fever called 'jungle yellow fever' has been recognized. It chiefly affects workers on the land and is not contracted in houses. There seems little doubt that human beings are not essential to the continuance of endemicity nor to the spread of this new type. As the President of the Yellow Fever Commission of the Office International remarks, it would seem that jungle yellow fever in man is an accidental occurrence in the course of an epizootic among lower animals.

Laboratory findings have shown that this jungle yellow fever virus can be transmitted from monkey to monkey by the *Aedes aegypti* mosquito which is the most important vector of the urban type of the disease. If, as all recent work indicates, the virus of jungle yellow fever is identical with that of the urban type of the fever, the position in India is that, in addition to the immense human reservoir for the virus, there exists

a vast monkey reservoir which could by no practical means be eliminated or controlled.

In regard to Africa, which is of primary interest to India in view of the rapid development of air traffic, investigations reveal that the disease is much more widespread than was generally considered to be the case. Positive mouse protection tests have been obtained in Egypt, the Anglo-Egyptian Sudan and in Uganda suggesting the presence of sporadic infection in the areas investigated. Those areas in which this test is positive but in which clinical cases of the disease, for one reason or another, have not yet been recognized are known as 'silent areas'.

It is therefore reassuring to read that in order to provide safeguards for this country, the Government of India in June and September 1936 issued notifications under the Epidemic Diseases Act which forbade the entry into India of any aircraft which has started from or alighted in a yellow fever endemic or 'silent' area, except such aircrafts which have obtained at Alexandria or Cairo a certificate of disinsecticization with 'Pyrocid 20' in the manner prescribed. These notifications also prohibited the entry into India of a passenger or a member of the crew of an aircraft within 9 days of his having been in an endemic or 'silent' area, unless he was protected by inoculation or by a previous attack of yellow fever.

The report gives further details of measures being taken not only to prevent infected mosquitoes reaching India from Africa, but also for the reduction of the yellow fever mosquito in the danger spots in India. Altogether the preventive campaign against yellow fever has a very serious bearing on the future welfare of India's millions. With the efficient prosecution of the measures in force and with the co-ordination of all those concerned, such as aircraft companies, port trust authorities, municipal councils, local boards and individual householders, it is hoped that the danger can be reduced to infinitesimal proportions and may, in fact, be entirely avoided.

The report gives a short account of the activities of the League of Nations Health Organization which continued to maintain its valuable service of epidemiological intelligence and public health statistics. A commission on biological standardization was engaged in working out international standards for a series of products, the assay of which could only be effected by biological methods. The malaria commission of the health organization has accumulated a wealth of specialized knowledge regarding the treatment and prevention of malaria by synthetic remedies. International courses of malariology were organized.

The health committee of the organization met in October and the Public Health Commissioner who is a member of the committee was able to be present, whilst he also attended the inter-governmental conference in the same month on biological standardization. The Government of India was also represented at a Pan-African health conference held at Johannesburg in November. The apprehension of the Government of India regarding the danger of entry by aeroplane of man and mosquito infected with yellow fever from Africa was clearly explained. Much information is required regarding the extent to which yellow fever is present in the African continent, and the conference made a strong recommendation regarding the necessity for further investigations on this important subject.

PUBLIC HEALTH WORKS

Successive reports of the Public Health Commissioner have emphasized the importance of environmental hygiene, and have emphasized the general failure of local authorities throughout India to provide good water supplies, good drainage and satisfactory means of removal and disposal of refuse and sewage. Until the local bodies are prepared to provide the funds for these primary essentials of environmental hygiene, the urban and rural population cannot hope to enjoy a reasonable standard of health. Undoubtedly, financial stringency in the year 1935 must have hampered the efforts of even the most enthusiastic and progressive committees. Looking towards future developments, it can be said that there is considerable scope for the employment by

these committees of trained sanitary engineers. But until it becomes clear that the public health schemes in the towns and districts will provide careers for whole time sanitary engineers, it is unlikely that many students of the engineering colleges will start specializing in this branch of their profession.

One of the most crying and widespread needs in India is the provision of a safe supply of drinking water. The report states that 88 per cent of the urban population in towns with a population of over 50,000, 57 per cent of the population in towns with a population between 30,000 and 50,000, and 19 per cent in those with a population below 30,000 enjoy the benefits of a reasonably pure water supply. Speaking generally, a protected water supply in rural areas is of rare occurrence.

In some provinces, the local bodies are inclined to assume that no improvement is possible without a grant from the Provincial Governments. The general idea among the villagers is that any improvement must be carried out by the local bodies. Both points of view are erroneous and the truth lies between the two. To provide efficient conservancy, adequate drainage and safe water supplies for the whole of India's population would seem to be a superhuman task. Much immediate improvement could however be brought about if the idea of self-help became more general. In many cases, the villagers through their own labour could bring about a marked improvement. The campaign for rural reconstruction which has been taken up with enthusiasm has as one of its principal objects the development of this idea of self-help among rural populations. On the other hand, where the resources of the village cannot deal with the problem, the local body must play its part, and what is urgently required in this connection is the drawing up of practical schemes which are not too ambitious.

LABORATORIES AND MEDICAL RESEARCH

The report covers the activities of the Central Research Institute, Kasauli, the All-India Institute of Hygiene and Public Health, Calcutta, the School of Tropical Medicine, Calcutta, the Haffkine Institute, Bombay, the King Institute of Preventive Medicine, Madras, the Pasteur Institutes in Kasauli, Coonoor, Shillong, Rangoon, Calcutta, Bombay and Patna. Most of these institutions publish their own annual reports, which should be studied in order adequately to appreciate the variety and scope of the numerous researches which are being made. While most of the institutes are maintained by the Central or Provincial Governments, the special funds for particular researches are largely provided by the Indian Research Fund Association.

India has an unenviable reputation amongst other countries as being the home of cholera. It is appropriate therefore that research work should be carried out with a view to elucidating the reasons why cholera continues in endemic and epidemic forms in this country. In 1935, cholera research was pursued intensively. The work was shared between the Central Research Institute, Kasauli, the All-India Institute of Hygiene and Public Health, Calcutta, the School of Tropical Medicine, Calcutta, and the Pasteur Institute, Shillong, co-ordination being arranged by a Cholera Advisory Committee. This work was of a highly technical nature and resulted in a distinct advance in our knowledge regarding the identification of the particular organism which is responsible for cholera in epidemic form in India. Enquiries regarding the value of bacteriophage in the prevention and treatment of cholera were continued, but the results remain elusive and unconvincing.

In the field of malaria, an intensive year's work on the part of the Malaria Survey of India is recorded. This included entomological investigations, field work and surveys, and an enquiry into the efficiency of anti-malarial drugs. Enquiries into the method of malaria transmission were carried out at the School of Tropical Medicine, Calcutta, while the All-India Institute of Hygiene and Public Health carried out a field enquiry with a view to evolving a cheap method of rural malaria control. Blackwater fever also was a subject of research at this institute. The Assam Medical Research Society carried out malaria enquiries, including an investigation

into the breeding cycle of the *Anopheles minimus* which is the principal vector of the disease in that province.

Nutrition research was conducted in the Indian Research Fund Association Laboratory at Coonoor and at the All-India Institute of Hygiene and Public Health; this work is dealt with in the section of the report devoted to that important subject.

Enquiries were conducted in the Haffkine Institute, Bombay, regarding the relative values of plague vaccines made from heat-killed cultures and those made from live avirulent cultures. The standardization of plague vaccine and other factors in connection with its manufacture were also studied.

Space does not allow of details being given regarding other interesting and valuable researches carried out in the different institutes covering the subjects of leprosy, anti-rabic vaccine, tuberculosis, kala-azar, snake venom, the value of indigenous drugs, anæmia of women, drug addiction, typhus, the incidence of cancer, the etiology of cataract, splenomegaly, epidemic dropsy, helminths and fungi.

It is clear to the reader of the Public Health Commissioner's report that India's future well-being and happiness are closely bound up with the activities and success of her workers in the field of medical research. It is true that with increasing knowledge new discoveries in the medical world have ceased to be as dramatic as in the past, but the research of to-day is no less necessary and no less valuable on that account. Any lowering of the standards maintained by the medical research workers in India will only result in the slowing down of India's progress towards better health conditions for her people. The Indian Research Fund Association has played a brilliant part in the past in the attainment of those high standards which have commanded the admiration of research workers in other countries. It is imperative that these standards should be maintained.

NUTRITION

The question of nutrition has been on the programme of the League of Nations since 1925 and, after a period of preliminary study, a report was published reviewing recent progress in this field and describing what the public authorities in a number of countries had already done or proposed to do. The assembly of the League expressed the opinion that the health organization should continue to develop its investigations into nutrition and nutrition problems in relation to public health, and that the other technical organizations of the League should continue their enquiries, especially as regards those measures which have already been adopted in various countries for improving nutrition and mitigating the plight of agriculture.

The work on nutrition has been the subject of four reports by the League of Nations and the whole problem is still under consideration both at Geneva and in practically every country of the world. India has taken its due share in this task and the Public Health Commissioner was able to assure the health committee at one of its meetings in 1935 that India would collaborate with its work in this field in every way possible.

The Indian delegation to the ordinary session of the Assembly of the League of Nations held in September 1935 also stressed the importance of the question of nutrition in relation to public health, and one of the Indian delegates remarked that the Indian Government was devoting special attention to the questions of rural hygiene and health and housing of the rural population, problems so vast that the end in view could not be achieved for many years to come. They therefore welcomed the prospect of the Conference on Rural Hygiene in the Far East. This conference was held during August 1937, and it is not divulging any secret to state that the problem of nutrition was considered in detail by a committee of that conference.

The first part of Section XII of the Public Health Commissioner's report includes an up-to-date description of what has been done in this field in India during the past two to three years and as will be seen covers the work done right up to its date of publication. The

first two pages of the note on nutrition give paragraphs from the May 1937 report of the health committee of the League of Nations in which the position is reviewed and which indicates the list of problems recommended for further study. These include: assessment of the nutritional state of children; nutritive food requirements during the first year of life; influence of climate on food requirements; the extent to which diets in common use fall below the standards recommended; and the optimum amounts of milk required at different ages. These subjects indicate the multifarious aspects which require consideration in dealing with what is a large and difficult problem.

In India, interest in the question of nutrition has grown rapidly, especially since the assumption of the Viceroyalty by His Excellency Lord Linlithgow, and it is to be noted that this country has by no means been behind others in the field of nutritional research. The Indian Research Fund Association has for some fifteen years past been financing research work on nutritional problems and Sir Robert McCarrison, the first Director of Nutrition Research in India, carried out pioneer investigations on different aspects of nutritional problems and demonstrated their importance to India long before the present world-wide interest was roused. The importance of many of the facts described and published years ago by Sir Robert McCarrison has, indeed, now only been generally recognized. The work which has been done within the last two years indicates that a very large proportion of the population of India is under-nourished, and that this mal-nourishment not only affects the mental and physical energy of the individual but increases the morbidity and mortality of the many infectious diseases to which the ordinary individual is subjected in this country.

The present Director of Nutrition Research in India has extended the work on nutrition to a remarkable extent. In 1935, for instance, a systematic survey of the nutritive value of Indian foodstuffs was begun in Coonoor and a few months ago a health bulletin was published which covered the results of that survey. The bulletin included tables giving the value of about 200 common Indian foodstuffs as regards their content of calories, proximate principles, calcium, phosphorus and iron; in addition, 160 foods were investigated for vitamin A and carotene content; a similar number of vitamin C content; and about 50 for vitamin B₁ content. That there is a great demand for information on this subject is indicated by the fact that within a few weeks the first edition of 10,000 copies of the bulletin, which had been wisely priced by the Government of India at the nominal charge of two annas, was completely sold out. Steps are also being taken to issue extracts from the bulletin in the form of leaflets, etc., both in English and the commoner vernaculars.

Dietary surveys are also being carried out both by the Coonoor and Calcutta research units. The preliminary results of these surveys in South India suggest that the diet of the average villager is even more deficient, from the standpoint of both quality and quantity, than earlier and more casual investigations had indicated, but such surveys take a very considerable time and have to be carried out with extreme care if they are to be of real value.

Attempts are also being made to study the effect on health and physique of different types of diet. To this end, enquiries have been carried out in day schools in South India. The Coonoor laboratories have also completed an enquiry into the 'state of nutrition' of some 5,000 school children in South Indian towns. This enquiry indicates that a high percentage of children is in a state of malnutrition, displaying symptoms of food deficiency disease. Striking evidence that average Indian children are in a subnormal 'state of nutrition' has also been provided by experiments with skimmed milk. These preliminary experiments indicate that skimmed milk, fed in comparatively small quantities, is a valuable addition to average South Indian diets. The fact that stomatitis, a common deficiency disease, disappears when skimmed milk is fed is of obvious importance. It must be remembered, however, that the addition of even small quantities of milk in the cheapest

form involves a considerable percentage increase in expenditure on food. Investigations on several other lines are under way, and it may be anticipated that these and others will give additional information for the guidance of those who are concerned with improvement in the nutritional state of both children and adults.

About the middle of 1936 the Governing Body, Indian Research Fund Association, decided to form a Nutrition Advisory Committee, the members of which should have special knowledge of the problems associated with human and animal nutrition. The committee, with the Public Health Commissioner as Chairman, held its inaugural meeting in Simla in June 1936, when it was honoured by the presence of His Excellency the Viceroy who opened the proceedings. The nutritional committee issued a report shortly after its meeting and copies were circulated to all Provincial Governments by the Government of India. The committee in the first place drew attention to the need for a preliminary survey of the 'state of nutrition in relation to the dietary habits of the people'; if the state of nutrition in India were to be improved. These preliminary surveys, it was recommended, should be carried out in representative areas throughout India. Emphasis was also laid on the Provincial Governments having at least one officer with special knowledge of the subject.

In accordance with the recommendation of the nutrition advisory committee the first course of training has been held at Coonoor, having been attended by a number of officers deputed by Provincial Governments. These officers have now returned to their provinces and it is to be hoped that their new knowledge will be of advantage.

The Governing Body, Indian Research Fund Association, in accordance with another of the recommendations made by the nutrition advisory committee have appointed an experienced officer whose duty will be to develop and maintain a closer liaison between human nutrition work and agricultural research. This officer, having completed his six months' training at Coonoor, is now working at the Imperial Agricultural Research Institute in Delhi, where he will keep in immediate touch with the research activities of workers in the agricultural field. At the present moment little attempt has been made to make any exact definition of the officer's duties and functions, but it is expected that time and experience will indicate the lines along which his activities can best be directed.

Another of the recommendations made by the nutrition advisory committee has been given effect to and three field workers on nutrition have received a training in Coonoor with special reference to dietary surveys; they will be engaged in different parts of India on this work.

Additional work was carried out during the cold weather of 1936-37 by Dr. Curjel Wilson, lately a member of the Women's Medical Service, under the auspices of the Royal Society of London, which gave her a grant from funds originally placed at the disposal of the Royal Society by an Indian philanthropist. The data collected by Dr. Wilson in the Punjab and Delhi Provinces are now under statistical examination and will shortly be available to the Governments concerned. Dr. Wilson is extending her work to other areas during the forthcoming cold weather and will not only visit Kashmir but will also make surveys in the Central Provinces and in Orissa. These surveys are, it must be remembered, the very basis of nutrition work, and it is essential for success that they should be prepared as accurately as possible. Although inaccuracies are difficult to avoid, every error detracts heavily from their value.

The nutrition advisory committee also recommended that an Assistant Director of Nutritional Research should be appointed in order to give the Director further time to develop and control new activities in addition to the experimental and laboratory research units which have during recent years continued to expand in different directions. This officer will shortly take up his appointment in Coonoor.

All these activities would be of little avail if the results obtained were not brought home to the people themselves. The subject of propaganda, or as His Excellency put it in his address to the nutrition committee, the need for practical application in the homes of the people of the fruits of research, is also being energetically pursued. It will be remembered that Sir Robert McCarrison published a small book entitled *Food* in 1923. This has gone through several editions and it has been translated into a number of vernaculars, and whilst it has been widely used by those in charge of hostels, boarding schools and similar institutions, further propaganda work has been done by means of the health bulletin already referred to. Whilst periodical notes, such as those issued from the nutrition laboratories on the value of skimmed milk, are issued to the press in the hope that the information contained therein will reach the people for whom it is intended, other arrangements are also under way, such as the preparation of series of coloured posters, etc. In the same direction, a certain amount of educational work by means of pamphlets and posters is being carried out by provincial public health departments and voluntary associations. But much more remains to be done before one can bring to the notice of the average villager the practical results of scientific research and get him so to adjust his diet as to give him the best value for his expenditure on food materials.

Some details are given in the report as to the expenditure incurred by the Indian Research Fund Association on nutritional research. The average cost of the maintenance of the nutritional research laboratory at Coonoor has amounted to over Rs. 82,500 per annum. Six other grants for nutritional research have been made to different workers, including those in Indian Universities, and in order to implement the recommendations of the nutritional advisory committee, the Indian Research Fund Association have earmarked an additional sum of Rs. 15 lacs.

DRUG ADULTERATION

Following on the publication of the Drugs Enquiry Committee's report in 1930, which comprised an exhaustive examination of the whole question of the control of the import, manufacture and sale of drugs and medicines in India, and a discussion in the Council of State during 1935, the Government of India again impressed on Provincial Governments the need for action and enquired whether, in view of the urgency of the problem, they would be prepared to adopt the recommendations made in the report. The establishment of a central drug-testing laboratory was also made the subject of reference.

As a first step towards the effective control of drugs and medicines in India, the Government of India have recently established bio-assay and pharmaceutical sections of a central drugs laboratory under the guidance of the Director of the Tropical School, Calcutta. These sections were opened in March 1937, being temporarily accommodated in the All-India Institute of Hygiene and Public Health. The technical staff includes a pharmacologist, a senior experimental assistant, a pharmaceutical chemist and a biochemist.

It will probably be necessary later on to open a further section for the testing of sera and vaccines; evidence already shows that these substances require a degree of control which does not yet exist in this country. It is obviously desirable that the drug control scheme should develop gradually, as experience indicates lines on which further advance is necessary.

It is to be noted, however, that one of the essential parts of the scheme is the development of a suitable laboratory in each province, as of course it is impossible for one central laboratory to deal with the whole of India. In addition, under the new Constitution, control of drugs is vested in Provincial Governments, but it will be necessary to evolve some arrangement by which co-ordination can be effected between Provincial Governments' laboratories and the Central Government's laboratory.

The Drug Enquiry Committee's report visualizes that the central laboratory will undertake commercial testing

of drugs for manufacturers and dealers on payment of fees. In a country like India where the drug manufacture industry is in its infancy, the expert advice such as will be available in the central laboratory should be of great assistance in the development of this important industry. A number of manufacturing firms already in existence in this country has at present no means for proper testing and standardization, and they will probably welcome the assistance which the Central Government's laboratory can give.

Correspondence

SIPHUNCULINA FUNICOLA (EYE-FLY).

To the Editor, *The Indian Medical Gazette*.

SIR,—In your January 1938 number, Mr. M. M. Syddiq has published a short résumé of the life history of the eye-fly, *S. funicola*. It is however necessary to mention that Jepson and Pinto (1927), in the Ceylon Government Agricultural Service, have previously studied the life history, and bred the flies artificially on a variety of dead organic matter: they lived as much as six weeks in captivity, and did not breed on growing plants, as is usual in the *Oscinida*, to which family they belong.

Later on, D. N. Roy (1928) found that they were breeding naturally in cattle sheds, where the earth was sodden with excreta, and Syddiq has restated this matter thus, 'the breeding place *par excellence* is moist mud, particularly that contaminated by decomposition of organic matter. The damp soiled earth around improperly kept pail latrines is a favourite breeding place; breeding has been found in badly-kept cattle stables and more frequently in connection with badly-kept and contaminated surface drains'.

As the natural source of the pest is an important matter in some districts, particularly in the tea gardens, it will be seen that Dr. Roy should be given prior credit for his observations.

It is scarcely necessary to advise on any course of action.

C. STRICKLAND, M.A., M.D.,
Professor of Medical Entomology.

SCHOOL OF TROPICAL MEDICINE,
CALCUTTA,

2nd March, 1938.

[Note.—Jepson and Pinto failed to find the natural breeding sites of these flies, but were able to breed them in the laboratory on decaying animal and vegetable materials.

D. N. Roy investigated the matter further by placing longcloth meat-safes over different sites. Some nine different types of site were tested, with the following result: 'Only dung and urine and sodden earth in cattle sheds yielded the flies and then on four occasions; only thirteen eye-flies in all were caught from these sites.

With this single experiment it cannot be said that finality on the subject of the breeding habits of eye-flies has been reached, and we are glad that M. M. Syddiq, who appears to have overlooked these earlier references, took up the matter again.

His conclusions appear to have been reached independently, as in answer to a letter in which we asked him for his authority for the statement regarding the breeding sites of eye-flies, he replied as follows:—

'Sir,

With reference to your letter of the 11th March, 1938, I have to inform you that different types of eggs are found at such places. Mud was collected and the

different types of eggs separated out and bred on boiled and separately. Details about the eggs were recorded and drawn beforehand. One particular type of egg—described in the text—ultimately developed into eye-flies. Later, eye-flies obtained in nature were made to breed on boiled and found identical. This has been repeated several times under rigid laboratory conditions with the same result. I cannot quote any authority for I have not come across any literature on the subject. I should be much obliged if anybody could point out to me any literature dealing with flies of this type and detailed laboratory technique about preservation of larvæ in their natural condition.

Yours, etc.,
M. M. SYDDIQ, M.B.B.S., L.R.C.P.,

D.T.M. & H. (Lond.),
Chief Malaria Officer,
Hyderabad, Deccan.

HYDERABAD, DECCAN,
24th March, 1938.

We believe that the sites mentioned by him do not by any means exhaust the possibilities for the breeding sites of these pests and we consider that there is still room for further work on the subject.—Editor, [M.G.]

PISTIA STRATIOTES AND MF. MALAYI

Sir,—In the control of human filarial infection of the type associated with *Mf. malayi* in the blood, Mr. Iyengar in the *Indian Medical Gazette* of May 1937 (pp. 300-307) and Drs. Sweet and Pillai in the *Indian Medical Gazette* of December 1937 (pp. 730-734) report striking success by biological means during the period 1933-37 under the auspices of the Government of Travancore. The object was simply the eradication of the water plant *Pistia stratiotes* as a species-sanitation measure directed against species of the sub-genus *Mansonioides*, which are the vectors of the disease in North Travancore. Rodenwaldt (1934), with vectors of *Mf. malayi*, and suggests control by eradicating *pistia* from swamps.

In Assam there are two hyperendemic foci of the particular type of filarial infection associated with *Mf. malayi*, one in the Surma valley and another in the Assam valley, that I have investigated, both comparatively limited in extent and the same species of *Mansonioides* are incriminated as carriers, i.e., *M. (Mansonioides) uniformis*, *M. (Mansonioides) indiana*, and *M. (Mansonioides) annulifera*. In Assam, however, the *pistia* plant is by no means the only agent in the life history of *Mansonioides*, but even more prominently there are the water hyacinth and the type of sedge grass growing in swamps and sluggish waterways known locally as *dol* grass, and there may be others. The larvæ and pupæ of these species are to be found abundantly in nature on the roots of the two last-named aquatic plants, even more so than on *pistia* roots, and *M. uniformis*, *M. annulifera*, and in addition from the younger forms, and there is no reason to suppose that *M. indiana*, which is closely related and very similar to *M. uniformis*, cannot be hatched in the same way. Furthermore, one heavily infected area has no *pistia* within about three miles.

It is obvious then that in Assam *pistia* eradication would not provide the beautiful example of species sanitation that it has done in Travancore, and when one considers the almost universal occurrence of water hyacinth and *dol* grass in the swamps and undrainable stagnant-water areas in the plains of this province the prospect is almost as depressing as it was before. When I add that in the areas mentioned, *Anopheles hyrcanus* var. *nigerimus* also is almost an 100-per-cent carrier of the infection, the problem becomes even more difficult.

The subject-matter of this letter and the incidence generally of both types of filariasis in Assam will be

amplified in an article to be published shortly by myself, but meantime I merely wish to point out that each focus of filariasis in a district, like malaria, constitutes a separate problem in the light of local conditions and it would be regrettable to generalize, and apply remedial measures empirically, without special investigation.

LABAC CENTRAL HOSPITAL,
DEWAN P. O.,
CACHAR,
9th March, 1938.

Yours, etc.,
G. FRASER.

Service Notes

APPOINTMENTS AND TRANSFERS

Appointment—Personal staff
The Viceroy and Governor-General has been pleased to make the following appointment on His Excellency's personal staff:—

To be Honorary Surgeon

Colonel A. F. Babonai, C.I.E., O.B.E., vice Colonel S. G. S. Haughton, C.I.E., O.B.E., V.H.S., vacated. Dated 28th January, 1938.

The Secretary of State for India has appointed Lieutenant-Colonel G. A. Khan to the Civil Branch of the I. M. S. from 1st April, 1937. He will count his seniority in Civil employment from the 5th June, 1930.

Lieutenant-Colonel H. H. Brown to be Officiating D. D. M. O. W., Army Headquarters. Dated 8th February, 1938.

Lieutenant-Colonel A. C. Craighead to be Officiating A. D. M. S., Bombay District. Dated 14th February, 1938.

Lieutenant-Colonel D. F. Murphy, M.C., to be Officiating A. D. M. S., Baluchistan District. Dated 17th February, 1938.

Lieutenant-Colonel J. C. Bharucha, Principal, Medical School, Agra, is appointed Officiating Civil Surgeon, Agra, in addition to his own duties from 21st February, 1938, vice Major Lucas.

On return from leave, Lieutenant-Colonel J. H. Barrett was posted on general duty at the General Hospital, Mandalay, from the 23rd February, 1938, a.m., and as Civil Surgeon, Mandalay, from the 1st March, 1938, vice Lieutenant-Colonel W. J. S. Ingram proceeding on leave.

Lieutenant-Colonel S. L. Patney, Superintendent, Presidency Jail, is appointed to act as Inspector, General of Prisons, Bengal, in addition to his own duties, during the absence, on leave, of Lieutenant-Colonel M. A. Singh.

Major J. Carrey, Civil Surgeon, Saugor, is reverted to the Military employment and posted to the Indian Military Hospital, Rawalpindi.

Major E. G. Hurd-Wood to be Additional Medical Officer, Army Headquarters Establishments. Dated 1st February, 1938.

Major B. N. Hajra made over charge of the Barisal Jail to Dr. G. De on the afternoon of the 1st February, 1938.

Major J. E. Gray, on the expiry of his leave, is posted on general duty at the St. George's Hospital, Bombay, with effect from 18th February, 1938, pending further orders.

The undermentioned Officers are reverted to Military duty:—

Major B. N. Hajra, on 14th February, 1938, posted to C. I. M. H., Wana.

Captain A. K. Gupta, on 14th February, 1938, posted to C. I. M. H., Wana.

Captain A. K. Gupta made over charge of Berham-pore Jail to Dr. B. N. Chakravarty on the forenoon of the 1st February, 1938.

Captain V. E. M. Lee whose services have been placed at the disposal of the Government of the C. P. and Berar has been posted as Civil Surgeon, Saugor.

Captain G. W. Miller whose services have been placed at the disposal of the Government of C. P. and Berar has been posted as Civil Surgeon, Chhindwara.

Captain B. J. Griffiths assumed charge of the Civil Surgeoncy of Jhansi on 5th February, 1938.

The undermentioned I. M. S. Officers were transferred to Civil employment:—

Captain B. A. Porritt, on 4th February, 1938, to Civil Madras.

Captain C. F. Garfit, on 22nd January, 1938, to Civil Punjab.

Captain G. W. Miller, on 1st February, 1938, to Civil Central Provinces and Berar.

Captain V. E. M. Lee, on 25th February, 1938, to Civil Central Provinces and Berar.

To be Captain (on probation)

Williams Sharp Davidson. Dated 1st January, 1938, with seniority as Lieutenant, 23rd December, 1933, and as Captain, 23rd December, 1934.

[This is evidently in supersession of the previous notification, *vide* page 190 of the March number—Editor, *I.M.G.*]

The undermentioned Officers are restored to the establishment:—

Lieutenant A. E. B. deCourcy-Wheeler, 1st January, 1938.

Lieutenant G. B. Jackson, 1st January, 1938.

Lieutenant C. W. Greene, 1st January, 1938.

To be Lieutenants (on probation)

1st January, 1938

William McIntyre Wilson, with seniority from 1st July, 1937.

William Loren Fennel, with seniority from 1st January, 1937.

Thomas Arthur Cunningham, with seniority from 1st January, 1937.

Desmond Rantzen Hanbury, with seniority from 1st January, 1937.

Francis Cleon Griggs, with seniority from 10th June, 1937.

Arthur Hamilton Booth.

James Walsh Lillico.

Duncan McCallum Black.

James Gordon Fife.

LEAVE

Colonel A. F. Babonau, C.I.E., O.B.E., A.D.M.S., Bombay District, proceeded on five months and one day's combined leave ex-India from 14th February, 1938.

Colonel A. C. Munro, A.D.M.S., Rawalpindi District, proceeded on two months' privilege leave from 21st February, 1938.

Lieutenant-Colonel W. J. S. Ingram is granted twenty-eight months' leave, preparatory to retirement, from the 1st March, 1938.

Lieutenant-Colonel E. S. Goss is granted privilege leave for two months with effect from 15th March, 1938, or date of availing combined leave on private affairs ex-India up to 25th September, 1938, pending retirement.

Lieutenant-Colonel C. M. Ganapathy, M.C., D.P.H., Director of Public Health, is granted leave for six months with effect from the 23rd March, 1938, or the date of relief.

Major T. H. Thomas, Officiating Professor of Medicine, Medical College, Calcutta, is granted leave for six months with effect from the 2nd February, 1938, in extension of the leave already granted to him.

Major E. S. S. Lucas, Civil Surgeon, Agra, on leave from 21st February, 1938.

PROMOTIONS

Lieutenant-Colonel to be Colonel

C. A. Wood. Dated 10th August, 1937, with seniority from 28th July, 1934.

Major to be Lieutenant-Colonel

A. K. Sahibzada, O.B.E. Dated 30th January, 1938.

Captain to be Major

G. Milne, I.M.S. Dated 4th August, 1937.

Promotion of the following I. M. S. Officers to the rank of Major is antedated as noted below:—

E. G. Hurd-Wood. Dated 30th November, 1934.

A. V. O'Brien. Dated 1st April, 1937, with seniority from 15th February, 1937.

H. S. Waters. Dated 4th February, 1938.

C. F. J. Cropper. Dated 8th February, 1938.

S. Lal. Dated 10th February, 1938.

RETIREMENT

Lieutenant-Colonel A. D. Stewart. Dated 13th January, 1938.

Notes

'TABLOID' FERROUS CHLORIDE, CITRATED

MANY authorities consider that ferrous chloride provides the most satisfactory means of administering iron. Hitherto, however, the use of this salt in medicine has been hindered by its tendency to rapid oxidation and consequent reduction in therapeutic efficiency. Experiments with various stabilizing agents have resulted in the introduction of citrated ferrous chloride now official in the *B. P. Addendum*, 1936. Burroughs Wellcome and Company issue the preparation as 'Tabloid' ferrous chloride, citrated, gr. 3, in bottles of 100. The product is sugar coated and is claimed to resist oxidation and deliquescence under all climatic conditions. It is directed to be taken after food with a copious draft of water.

AN ATTRACTIVE CALENDAR

We have received through their agents in India a copy of the very attractive calendar issued by Messrs. Cow and Gate, Limited, makers of the well-known infants' food. This is a reproduction of a portrait of the two Royal Princesses, Elizabeth and Margaret Rose, and is a most tasteful and artistic production, free from advertising matter as befitting such a subject.

Publishers' Notice.

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors *ask for them at the time of submitting their manuscripts*.

Communications on Editorial Matters. Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to 'The Indian Medical Gazette', Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers (if available) for the previous year Rs. 2-8 each, and all other back numbers Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, nor creased, in transit.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

THE ANÆMIAS IN PREGNANCY

A HÆMATOLOGICAL, CLINICAL AND STATISTICAL STUDY

By SUJATA CHOUDHURY, W.M.S.

Lecturer in Medicine, Women's Medical School, and
Physician, Lady Lyall Hospital, Agra

and

VANMALI S. MANGALIK, M.D. (Luck.), D.C.P. (Lond.)

Lecturer in Pathology, The Medical School, and
Pathologist, Thomason Hospital, Agra

WHILE numerous references had been made in other countries, as early as 1919, to the peculiar character of anæmia associated with pregnancy (Osler, 1919; Bardy, 1924; Larrabee, 1925), the importance of this problem has only been appreciated recently. The first account of this condition in our country was published by Margaret Balfour in 1927, who carried out an enquiry by issuing a number of questions to various hospitals, and studied some cases in the hospitals of Bombay. No systematic hæmatological study had been done in her cases. Mitra (1931) published a report of cases of anæmia of pregnancy from the Chittaranjan Seva Sadan with a post-mortem study of one case, and clinical notes on 86 cases.

Wills in the same year (1931) drew attention for the first time to the existence of a 'pernicious anæmia' of pregnancy which in her opinion closely resembled the tropical macrocytic anæmia. She published a report of about six cases, and stressed the recovery of these cases with marmite.

Recently, Mitra (1937) has published a report of a large series of cases of pregnancy associated with anæmia, and has tried to classify these into various clinical types.

The first systematic study from the hæmatological point of view has appeared very recently (Napier and Billimoria, 1937), an 'analysis of the hæmatological findings in 52 cases of anæmia amongst pregnant tea-garden coolie women'.

The immense importance of the problem and the fact that the incidence of anæmia in pregnant women in our country seems to be more than in other countries, and also that little hæmatological study has been done on these cases in our country, may be some justification for the addition of this paper to those already published. As far as we know, no paper has appeared from the United Provinces dealing with this subject, and it is hoped that the following observations will be of help, however meagre, in the ultimate elucidation of the cause of this condition, which is responsible for so much ill health and mortality in the women of our country.

The type of material used in our cases differs from Napier's, in that in all our cases

there was no discoverable cause of anæmia in these women, such as a history of chronic malaria or kala-azar, or any helminthic infection. Stool examination for ova of intestinal parasites was negative in all cases.

Material on which investigations were carried out

In all 41 cases have been investigated. Cases were all from the Lady Lyall Hospital, Agra, and were admitted during the months of July to December 1937. All new patients were examined soon after admission by one of us (S. C.) and their hæmoglobin estimated at the bedside by Tallqvist's blotting-paper method, and only those cases that showed a hæmoglobin value of less than 50 per cent were investigated more fully and included in this series. The majority of the patients belonged to the poorer or lower middle class of people. The hospital is one of the chief maternity hospitals in the town and makes provision for *purdah*-observing patients as well. Most of the Indian patients who seek hospital aid are suffering from severe grades of anæmia and the minor grades of anæmia are seldom met with in the wards.

In addition to the complete investigation of the 41 cases, a statistical survey has been made from two years' records of the Lady Lyall Hospital with a view to working out the incidence of age, seasonal variations, relation to number of pregnancy, etc. No attempt has been made to classify those cases which were admitted before July 1937 into hæmatological types, because complete blood records were not available.

Investigation

All cases were subjected to a thorough physical examination and the various systems carefully searched for any abnormality, though no x-ray examination could be made. A complete hæmatological examination was undertaken before the treatment was started.

All blood examinations were made on venous blood, partly because it is more convenient and accurate to work on venous blood and partly because all normal hæmatological standards, both in this country and abroad, have been based on venous blood and the examinations were carried out by recent generally accepted methods*.

Incidence of anæmia with pregnancy

Total number of cases confined in 1936 and 1937 ..	2,400
Total number of cases which showed anæmia ..	126
Incidence of anæmia with pregnancy	5.6 per cent

Age incidence

The accompanying chart (figure 1) shows the age distribution of anæmia. It occurs between

*In the paper, as submitted, a description of the technique was given, but we have omitted it in the interest of space.—EDITOR, J. M. G.

15 and 40 years, and is frequent between the ages of 15 and 30 years, with a maximum incidence between 20 and 25 years, which corresponds with the maximum child-bearing period.

Fig. 1.—Age incidence.

Religion or caste

With this is linked the factor of vegetarians and non-vegetarians. All Hindu women in this series were strict vegetarians. Both Hindu and Mohammedan patients came from a similar class of society, the lower middle class. The impression so far has been that the anæmia is far more common amongst Hindu women. Balfour (1927) has also made a similar observation. A close study of the figures reveals that it is equally common in both the classes. This apparent low incidence of anæmia in Mohammedans is due to the smaller number of Mohammedan women seeking admission to the hospital for confinement.

Total confinements	Confinements with anæmia	Percentage
Hindus .. 1,750	90	5.1
Mohammedans .. 540	34	6.3
Others .. 110	2	1.8

Relation of anæmia to number of pregnancies

Figure 2 shows the greater incidence in primiparæ and the incidence of anæmia decreases in further pregnancies. Twenty-four cases were in primiparæ, 14 in the second pregnancy and more or less the same number in the third, fourth and fifth pregnancies. Mitra (1937) also observes the greater incidence in primiparæ.

Seasonal variation

Much seems to have been made of seasonal variation and incidence of anæmia with pregnancy. Mitra (1931, 1937) in Calcutta, Balfour

(1927) and Wills (1931) in Bombay found this disease more prevalent during the second half of the year. Mudaliar (quoted by Mitra, 1937) has found it more prevalent in the hottest part of the year. We, on the other hand, find that the incidence of cases of anæmia seems to

Fig. 2.—Relation to number of pregnancies.

be highest in the months of August to October, and this period also corresponds with a relative increase in number of cases confined in the hospital. The accompanying chart (figure 3) shows the seasonal variation of confinement cases and anæmia cases. There seems to be no real seasonal variation in anæmia cases, and

Fig. 3.—Seasonal variation in confinement cases and anæmia cases.

there is no reason why there should be more anæmia cases in the coldest part of the year in one province and the hottest part of the year in another, in the same country. As far as we know, anæmia in pregnancy is not due to an

infective process. It is, in all probability, a deficiency anæmia, and, as such, we fail to find any explanation for the apparent seasonal variation reported by other workers.

Months of pregnancy and anæmia

Months of pregnancy	Cases of anæmia
5th and 6th	2
7th and 8th	36
9th and 10th	88

It will be seen that most cases came to the hospital during and after the seventh month of pregnancy, when the associated symptoms compel them to seek hospital aid. It is, therefore, difficult to say when the anæmia actually starts.

The analysis of 41 cases, investigated in this series, is as follows :—

Months of pregnancy	Macrocytic cases	Microcytic and mixed type
5th and 6th	2	0
7th and 8th	9	0
9th and 10th	16	14

This shows how macrocytic cases have a tendency to seek hospital aid in the earlier months, while the microcytic cases can go on to the ninth and tenth months without being compelled to seek hospital admission. It is perhaps not necessarily due to an earlier onset of the one type as opposed to the other, but because the severe constitutional symptoms, such as dyspnoea, œdema, and general depression, appear early with more severe anæmia of the macrocytic type and compel patients to come to hospital early.

Infant mortality

Fifty anæmic women confined, out of a total of 126 in two years, lost their babies. Most of the babies were born quite healthy, but they died during the first three to four weeks. This seems more than incidental. In the present series of 41 patients, 16 babies died and all of them of mothers who were suffering from macrocytic anæmia (27 cases), an infant mortality of over 50 per cent. Going carefully over the hæmatological findings of these cases, one finds that the infant mortality is not related to the degree of anæmia. Some mothers with a count of over 2 million red cells lost their babies, while in others with a count as low as four hundred thousand red cells the babies survived.

Classification

Various authors have classified anæmia in pregnancy into various types :—

Wintrobe (1934) classifies anæmia of pregnancy into :

(i) Macrocytic, (ii) Normocytic, (iii) Simple microcytic, and (iv) Microcytic hypochromic.

Vaughan (1936) classifies them into various types of deficiency dyshæmopoietic anæmia and hæmolytic anæmia.

Adair, Dieckmann and Grant (1936) have proposed a simpler classification of (i) 'physiological' anæmia, (ii) hypochromic (subnormal hæmoglobin), and (iii) macrocytic, with a large mean cell volume and which they think is associated with toxæmia of pregnancy. Smallwood (1936) gives a logical and complete classification of anæmia and draws attention to the physiological type associated with hydræmia.

Mitra (1937) has grouped anæmia cases on the basis of some clinical data, such as anæmia of pregnancy associated with conditions like malaria, kala-azar, etc., whether in active or latent form, or cases without any clinical evidence of any of these conditions responsible for anæmia, which he names the idiopathic group. Napier and Billimoria (1937) have grouped their cases as :—

(i) Hyperchromic with marked anæmia.

(ii) Hyperchromic with slight anæmia.

(iii) Hypochromic microcytic anæmia.

(iv) Orthochromic normocytic anæmia which is not a distinct group.

There being some uncertainty about the cell volume estimations (the centrifuge was not efficient enough for the work), Napier grouped them according to the degree of hæmoglobin content of cells (MCH) rather than according to their size (MCV).

All these classifications have their own advantages and disadvantages. During the last few years, it has become recognized that most of the common types of anæmias are deficiency anæmias, due to the lack of one of the two main hæmopoietic substances, iron and the 'P. A.' factor (elaborated in the stomach from the interaction of the extrinsic and intrinsic factors); in the latter, the lack may be of either the extrinsic or intrinsic factor, or both. It is also recognized that iron deficiency leads to a microcytic hypochromic anæmia with a low MCV and a low MCH, and that the deficiency of either the extrinsic or intrinsic factor leads to a macrocytic hyperchromic anæmia, with a high MCV and a high MCH.

Wintrobe's hæmatocrit method of estimating mean corpuscular volume is becoming increasingly popular in laboratories. This is a method for estimating, with a fair degree of accuracy, the mean cell volume. The method is simple and can be used for routine work as well, without undue strain on the worker. It is not so elaborate and strenuous a technique, demanding hours of concentrated work, as is Price-Jones's method of determining mean cell diameter and is more reliable and accurate than the halometer.

In view of the above, it seems justifiable to propose a method of classification which is based on determination of mean corpuscular volume as this will be easy for grouping the cases, and practical for following a specific line of treatment. It is proposed to group them as :—

(1) Macrocytic hyperchromic anæmia, characterized by high MCV of over 90 c.µ. and MCH of over 29 γγ.

(2) Microcytic hypochromic anæmia with a low MCV and a low MCH.

(3) A mixed group—characterized by hæmatological findings which do not conform to any one of the two types, the MCV is in most cases on the higher side of normal, and the MCH is lower than normal. They are indicative of a dual deficiency of both the hæmatin principles, iron and the P. A. factor.

The grouping of 41 cases in the present series was as follows :—

	Cases
(i) Macrocytic hyperchromic ..	27
(ii) Microcytic hypochromic ..	6
(iii) Mixed type ..	8

Clinical findings

The macrocytic hyperchromic group.—This forms the biggest group of anæmia cases associated with pregnancy. It has been given different names by different authors—'pseudo-pernicious anæmia of pregnancy', 'grave hæmolytic anæmia', 'tropical macrocytic anæmia of pregnancy'.

This type seems to be far the most common—27 cases as opposed to 14 cases of the other types, in a period of six months. Clinically, the cases were characterized by marked pallor of the face, conjunctiva and other mucous membranes, and a greenish complexion (lemon yellow). Most of the cases looked ill, restless and dyspnoic; dyspnoea was a sort of gasping for breath or air hunger. Most of them had a low intermittent fever. The general condition was so characteristic that it was possible, in most cases, to guess the hæmatological group.

Gastro-intestinal symptoms.—These were prominent, 20 cases complained of diarrhœa—about 15 to 20 motions a day. Stools were watery, without blood or mucus, and microscopical examination did not show any evidence of a dysenteric or helminthic infection. We were unable to trace any seasonal variation in the gastro-intestinal symptoms. The diarrhœa usually responded to liver treatment. Cases 5 and 17 were achlorhydric (case 17, even after histamine injection) and their diarrhœa, which was of a severe type, stopped after administration of dilute hydrochloric acid.

Vomiting was not a marked feature. None of them had it while in hospital, though a few gave a history of vomiting before admission to the hospital.

Spongy gums were noticed in most cases. Two cases (5 and 17) had swelling and bleeding from the gums. No soreness of the tongue was observed in any case.

The spleen was enlarged in 15 cases, varying from just palpable to about 5 finger-breadths below the costal margin. Twelve cases had no enlargement of spleen. History of fever with rigor was obtained in five cases. The spleen was soft and a reduction in size was noticed after treatment (except in the five cases with a previous history of malaria).

Cardio-vascular changes were marked. No radiological or electrocardiographic examinations of the heart were done. The apex beat was displaced outwards, indicating an enlarged left ventricle. Systolic hæmic murmur was heard at the pulmonary and mitral areas in all the cases. In four cases (5, 17, 22 and 39) an aortic-diastolic murmur was heard, conducted down the left border of the sternum. The murmur was highly suggestive of aortic leak, which suggestion was strengthened by the high pulse pressure, a collapsing pulse, and increased pulsation in the carotids. The Wassermann reaction was negative and no history of previous rheumatic infection could be obtained. After treatment, as the anæmia and the general condition improved, the diastolic murmur also disappeared.

Some cases showed signs of congestive heart failure, such as fullness of the veins in the neck, epigastric pulsation, enlarged tender liver, and crepitations at the bases.

Edema was present in all the cases. It was generalized but more marked in the lower extremities. Some cases had ascites as well.

The nervous system did not show any subjective or objective signs.

The microcytic hypochromic and mixed groups.—These cases formed a contrast in clinical picture to the first group. Their complexion lacked in the 'lemon yellow' tint, though pallor was marked and hæmoglobin values as low as 4 gm. (30 per cent) were encountered; the patients never presented the ill, restless appearance of macrocytic cases. Dyspnoea and œdema were of a mild degree; they had no fever, nor were their gums spongy. There was no ascites. Cardio-vascular symptoms were not so marked; enlargement of the heart was detected only in one case; only systolic murmurs could be heard. Gastro-intestinal symptoms, such as diarrhœa and vomiting, were absent. The spleen was not enlarged in any case, nor was the liver palpable. No koilonychia was noticed.

Hæmatological findings

The red cell counts.—In the macrocytic group these were comparatively low (the majority below 2 millions, 10 cases below one million); the microcytic group had counts between 2 and 3 millions, while they were variable in the mixed group.

The mean corpuscular volume (MCV) and the mean corpuscular hæmoglobin (MCH).—These were characteristically high in the macrocytic cases. The MCV in most cases ranged over 95 c.µ. and values as high as 235 c.µ. were obtained. The MCH was over 30 γγ in all cases and in the majority between 35 and 45 γγ. The microcytic group showed a low MCV between 60 and 80 c.µ. and MCH between 11 and 21 γγ. In the mixed group MCV was on the higher side of normal, ranging between 90 and 103 c.µ. and MCH on the lower side of normal, between 22 and 27 γγ.

Mean corpuscular hæmoglobin concentration (MCHC).—In the microcytic and mixed group this was below 30 per cent in all cases, and over 30 per cent in most cases of the macrocytic group.

The reticulocyte count.—This was extremely variable and did not point to any significant difference between the various groups.

Morphology of the red cells.—The macrocytic group showed apparent megalocytosis in severe cases, and anisocytosis and poikilocytosis were marked. Vacuolation of red cells was a characteristic feature of the microcytic group and some of the cells were mere empty envelopes. In the mixed type, one noticed some cells which were well filled, and also anisocytosis and poikilocytosis and also vacuolation of red cells. Nucleated red cells, primary erythroblasts, and megaloblasts were encountered in the macrocytic cases with counts in the neighbourhood of 1 million. It was rare to find these in the other groups. Normoblasts were seen in all the groups.

Total white cell count.—This did not reveal any significant difference in the various groups. The majority of the cases showed a low leucocyte count, of the order of 3 to 7 thousand per c.mm.

The differential white cell count in all the cases showed a relative increase in lymphocytes. In some macrocytic cases, it was noticed that the differential count returned to normal as the anæmia improved.

Van den Bergh's reaction.—The direct reaction was negative in all cases. The indirect was positive in 20 cases of the macrocytic group and in 4 cases of the mixed group. No quantitative estimation of blood bilirubin was done. All the microcytic cases had a negative indirect reaction.

The urobilin test in urine was positive in 6 cases of the macrocytic group, and 2 of the mixed group. It was negative in all cases of the microcytic group.

Gastric analysis.—We were unable to perform a gastric analysis in as many cases as we would have liked. Some of the cases were too ill on admission to be subjected to this examination, and, as soon as they felt better, either they refused the test or left the hospital. Gastric

analysis was done on 18 cases in all and the findings could be tabulated as follows :—

Type	Achlorhydria	Normal	Low side of normal	High side of normal	Hypochlorhydria	Hyperchlorhydria
Macrocytic ..	2	1	2	5	2	1
Microcytic	3	1
Mixed ..	1

Out of these achlorhydric cases (5, 17 and 29) only two could be tested after histamine. Case 17 (macrocytic) remained achlorhydric and case 29 (mixed) secreted free hydrochloric acid after histamine.

The numbers are small, but the results do not indicate any distinctive or characteristic feature, except that most have free hydrochloric acid.

Wassermann reaction.—This was negative in all cases, except in cases 33 and 44, both of the macrocytic type.

Urine.—A catheter specimen was examined in all cases for albumin. It was negative in all cases, except three (15, 25, and 44). In case 15 urine was loaded with albumin and showed granular casts. She had marked vomiting and showed maniacal symptoms on the third day after confinement. She was taken home by her relatives and is said to have died the same day. Blood pressure readings of the three cases are tabulated below :—

Case	Albumin	B. P.	Vomiting
15	++	130/106	++
25	+	120/80	—
44	+	105/50	+

Treatment and course

General treatment was started soon after admission, and consisted of the usual nursing, good and light diet, and rest in bed. All cases were given glucose (pure B. P.) 5iv every 4 hours in water with lime juice or in milk with the feeds. Strychnine and camphor in oil subcutaneously were given as cardiac stimulants, when indicated.

Blood was taken and examined as soon as possible after admission, and the specific treatment was instituted only after the hæmatological examination. As far as possible only one hæmatinic drug was used in one case and the progress checked by frequent blood examinations. Teaching work and routine duties did not permit us to work out the reticulocyte response of the patients after treatment, as we would have liked to do.

Macrocytic cases were treated with one of the following preparations :—

- (a) Marmite (orally).
- (b) Neo-Hepatex (Evans), intravenous or intramuscular injections.
- (c) Liver extract (P. D. & Co.), intramuscular injections.
- (d) Campolon (Bayer), intramuscular injections.

Marmite.—Lucy Wills (1933) stressed the importance and value of marmite in 'pernicious anaemia of pregnancy', and showed how a sharp reticulocyte response and marked improvement was noticed in the majority of the cases with counts even as low as 1 million. Napier (1936) also showed how tropical macrocytic anaemia in non-pregnant women and men responds to treatment with marmite. We are not in a position to question the findings of Wills with regard to the efficacy of marmite, but we believed that our cases were far too ill and required more energetic methods for the restoration of the blood picture than oral administration of marmite. Most of the women sought hospital admission either at full term or showed indications of a premature labour. Some of them were moribund and others would not take marmite with its peculiar flavour, smell or taste. Hence we resorted to other methods of treatment, such as injection of liver preparations.

One case (37) was, however, treated with marmite 5ii every four hours, for one week. We were satisfied that the drug was taken by the patient. The patient failed to respond after a week's treatment, the blood examination showed no improvement. The patient's condition became worse after confinement (7th day after marmite treatment). The red cell count came down to 0.3 million; we tried intravenous hepatex, but the patient died.

Neo-Hepatex (Evans).—In all, 18 patients were treated. Neo-Hepatex was given intramuscularly, 2 to 4 c.cm. according to the severity of the case, daily for about 10 days, on an average.

Three cases with a count of less than 0.5 million were given intravenous hepatex; 5 c.cm. diluted in 5 c.cm. saline were injected very slowly. Two cases with a low count in the neighbourhood of 0.5 million could not be given intravenous hepatex; they died after 2 or 3 intramuscular injections. In all, 14 cases showed marked improvement after treatment with neo-hepatex, 2 left the hospital before treatment, and 2 died. Dramatic improvement was seen even in severe cases (5 and 22) after 24 hours of intravenous hepatex. The restlessness, dyspnoea and even the oedema showed remarkable decrease, and the general condition steadily improved on intramuscular injections.

Campolon (Bayer).—Five cases (14, 20, 24, 43 and 45) were treated with campolon, 4 c.cm. intramuscularly for 4 days, followed by 2 c.cm. for about 10 or 12 days in severe cases (24 and 43). In others, the dose varied according to the

severity of the case. Improvement was observed in all the cases.

Liver extract (P. D. & Co.).—This was given in two cases, 2 to 4 c.cm. intramuscularly for a few days. We failed to notice any clinical or hæmatological improvement in either after a week's treatment. Unfortunately both the cases left the hospital against medical advice.

Microcytic cases.—These were treated with iron ammonium citrate gr. xxx *t.i.d.* in mixture form. There was, in all cases, good response, and it was followed by marked clinical and hæmatological improvement from about the 3rd or 4th day. The mixture was well tolerated by patients, and, contrary to the idea entertained by some, was not attended by any gastro-intestinal disturbances. In none of the cases treated was hydrochloric acid administered to increase the absorption of iron.

The mixed group cases.—These were treated to start with by intramuscular injection of Neo-Hepatex for about a week, followed by administration of iron ammonium citrate. In most cases this was followed by improvement in the general condition and blood picture. The hæmoglobin went up and the MCV tended to come within normal limits.

Blood transfusion.—This was not resorted to in any case of this series. Even severe cases, we believe, are capable of recovery with such drugs as intravenous hepatex, followed by adequate doses of liver preparations by the intramuscular route.

Discussion

The problem of the anæmias in pregnancy has a special significance for those working in our country. While a large number of pregnant women in England and other countries suffer from anæmia during pregnancy, the anæmia is, in the vast majority of cases, an iron-deficiency anæmia due to a chronic blood loss and deficient intake of iron. This type of anæmia may be seen in this country, but seldom necessitates admission of pregnant women into hospitals for serious toxic or cardio-vascular symptoms. The type of anæmia which is common in pregnant women in this country is the 'grave type' of anæmia, named differently by various authors. In our present series of 41 cases, 27 cases were of macrocytic or the 'grave type'. To discuss the pathogenesis of this type of anæmia is not within the scope of this paper which is meant to be a study of clinical and hæmatological findings of the anæmias associated with pregnancy. There are a few facts, however, which are worth mentioning.

Lucy Wills (1931-1933), who named these cases tropical megalocytic anæmia of pregnancy, tried to distinguish them from true Addisonian pernicious anæmia by a few laboratory findings. The chief of these being :—

- (i) A negative indirect van den Bergh reaction,
- (ii) the absence of urobilin in the urine,

(iii) leucocytosis, and (iv) the presence of free hydrochloric acid in the stomach.

Napier (1936) reported positive indirect van den Bergh reaction and excess of urobilin in urine in 9 out of 11 cases of tropical macrocytic anaemia studied by him in men and non-pregnant women. The leucocyte count of his cases was on the lower side, the majority having a count between 3 and 6 thousand per c.mm. The cases, that he has studied, differ from cases of true Addisonian pernicious anaemia inasmuch as usually they show free hydrochloric acid in the stomach and are of a lower age group (20 years to 32 years).

In the present series of 27 cases of macrocytic anaemia (proved by determination of MCV), 20 had a positive indirect van den Bergh reaction and 6 had urobilin in the urine. The majority of the cases showed a leucocyte count below 5 or 6 thousand, a good many could be said to have leucopenia (3 to 4 thousand). Free hydrochloric acid was present in all except two cases of those examined.

Our cases thus show practically identical laboratory findings to Napier's cases of tropical macrocytic anaemia in men and non-pregnant women, except for cases 5 and 17—both of which were achlorhydric. Case 5 was a woman of 20, with a high leucocyte count and achlorhydria which was not confirmed by histamine injection. Case 17 was 35 years of age, she had a total white count of 3,600 per c.mm., a relative lymphocytosis (66 per cent), a positive indirect van den Bergh reaction, and an achlorhydria persistent after histamine injection. Her blood examination showed MCV 123.8 c.μ; MCH 42.6 γγ; MCHC 34.8 per cent; reticulocytes 0.8 per cent; anisocytosis and poikilocytosis were present. One primary erythroblast and one normoblast were present per 100 leucocytes. She gave a history of a similar grave anaemia during her confinement last year, when she was treated in this hospital. In our opinion, the case was one of Addisonian pernicious anaemia complicated or precipitated by pregnancy. We are fully conscious of the opinion held by some eminent medical men in India that true Addisonian pernicious anaemia is very rare or does not exist in India.

The presence of a positive indirect van den Bergh reaction in Addisonian anaemia is not quite well understood. Some attribute it to the large size of the cells which are broken down more easily, though red cell fragility has been found to be normal. There seems, therefore, no justification for the view held by Wills that these cases are characterized by absence of positive indirect van den Bergh reaction, when we realize that the ultimate result of lack of either extrinsic or intrinsic factor leads to the lack of the same hæmopoietic principle (P. A. factor) and is characterized by macrocytosis. This view is also held by Napier (1936).

We, therefore, believe that the macrocytic anaemia in pregnant women, the so-called 'anaemia of pregnancy', is identical hæmatologically with tropical macrocytic anaemia as reported by Napier (1936). There is nothing characteristic or distinctive about the anaemia to be regarded as a separate entity. Both are characterized by a high MCH and MCV, a positive indirect van den Bergh's reaction, the presence of urobilin in the urine, and a low leucocyte count. They differ from the Addisonian pernicious anaemia in having free hydrochloric acid in the gastric secretion, and the absence of neurological lesions.

Like the tropical macrocytic anaemia, perhaps the macrocytic anaemia in pregnancy is also due to a lack of extrinsic factor in the diet of these women. Pregnancy either complicates or probably acts as an additional cause by increasing the demands on the body for hæmopoietic substances.

Whitby and Britton (1937) think that iron deficiency is most commonly met with in temperate climates, and that in the tropics it is more common than macrocytic anaemia. De (1930) stated that in Bengal nearly all the anæmias of pregnancy are of the secondary type, and that the average hæmoglobin of a Bengali woman is about 7 grammes per cent (50 per cent Haldane). The lower incidence of hypochromic anaemia associated with pregnancy in Indian women has been a surprise in this extensive study of 'Anaemia in poor class women' of Aberdeen, and also of the 'Hypochromic anæmias of pregnancy'. The demands for iron during reproductive life depend on the following factors:—

1. Blood loss during menstruation.
2. Supply of iron to the fœtus, uterus, and placenta during pregnancy.
3. Blood loss at parturition.
4. Iron content of milk during lactation.

Fullerton (1936) has also shown that by a quantitative study of the loss of iron due to menstruation and pregnancy it is clear that the diets of poor women are very frequently inadequate to compensate for the iron demands of reproductive life.

Meat being a very important source of iron in the diet of non-vegetarians in this country, one believes that the daily intake of iron in the vegetarians is comparatively very low and inadequate. This low intake of iron, coupled with menstrual blood loss, and repeated and multiple pregnancies and parturition, ought to bring about a negative iron balance and a hypochromic anaemia in the vegetarian Indian women. It is surprising, therefore, that amongst women confined in the Lady Lyall Hospital from July to December 1937 only about one dozen cases of anaemia indicative of iron deficiency were seen.

Relation of anæmia and 'toxæmia' of pregnancy

The idea seems to be prevalent that the so-called 'toxæmia' of pregnancy plays a part in the causation of anæmia. Balfour (1927) stated that anæmia of pregnancy was due to a 'toxæmia due to products of conception', and compares well with eclampsia inasmuch as both occur during the second half of pregnancy and in primiparæ. Mitra (1937) remarks, while discussing the value of glucose therapy in the treatment of such anæmia, that 'glucose acts as a detoxicating agent, neutralizing the toxin which seems to be one of the causative factors in the anæmia of pregnancy'. While not denying the existence of toxæmia in cases with pre-existing renal disease or in the pre-eclamptic and eclamptic conditions, we believe that the 'toxæmia' referred to in connection with these grave cases of anæmia is more the effect than the cause of the anæmia. To us, dyspnœa, or air hunger, restlessness, œdema, and even fever in some cases appear to be due to anæmia and the associated cardio-vascular disturbances. We have noted how in all cases the institution of appropriate anti-anæmic therapy is followed by a general feeling of well-being. They feel better and better as the anæmia improves and all the so-called 'toxæmia' symptoms, even fever, disappear. We freely administered glucose to our patients, and believe in its efficacy—not as a 'detoxicating' agent, but as a drug of immense value to the myocardium. Jocelyn Moore and Pillman-Williams (1936) undertook an investigation into the association of anæmia with toxæmia and found that the incidence of toxæmic signs or symptoms is much lower in iron-treated cases than in controls, and that when the hæmoglobin value is kept in the region of 90 per cent, the incidence of toxæmia is low.

The conception of toxæmia has been carried so far as to advocate termination of pregnancy for the treatment of anæmia. 'Cure is never vouchsafed', they believe, 'unless the pregnancy terminates'. The improvement observed after the termination of pregnancy or after confinement is not due to absence of 'toxic products from the fœtus', but to the cessation of extra demands for hæmopoietic principles thrown on the already exhausted and poor resources of the mother. We believe that cases can show good improvement with appropriate treatment and can go on to full term without any 'toxæmic' signs. Case 22 was admitted on 7th September with a red cell count of 0.66 million, MCV 132.1 c.µ. MCH 41.6 γγ. She was gravely ill and in the 8th month of pregnancy. She was treated with intravenous and intramuscular hepatex, and was discharged on 23rd October with nearly 4 million red cells—MCV 86.9 c.µ. and MCH 28.7 γγ. She was told to take iron ammonium citrate at home and was delivered of a healthy child on 27th

November in the hospital without any untoward symptoms.

The name 'anæmia of pregnancy' appears to be misleading inasmuch as it gives the student of medicine the impression that the anæmia has some characteristic hæmatological and clinical features, directly brought about by pregnancy. We fail to find any evidence to show that anæmia in pregnant women is different from those of non-pregnant women or men. The macrocytic hypochromic group is hæmatologically identical with the tropical macrocytic anæmia as described by Napier (1936). The microcytic group is due to an inadequate iron intake of women made worse by pregnancy and parturition. Pregnancy either complicates or precipitates the anæmia owing to the demands of the growing fœtus on the hæmopoietic reserves of the mother.

Hence, we would prefer the use of the term 'anæmia (or anæmias) in pregnancy' to 'anæmia of pregnancy'.

Summary and conclusions

1. A statistical survey of anæmias in pregnancy from the records of a maternity hospital shows that in 2,400 confinements in two years the incidence of anæmia is 5.6 per cent.
 2. It is equally common amongst the Hindus and Mohammedans.
 3. It is more common in primiparæ, and the maximum age incidence is between 20 and 30 years.
 4. There is no seasonal variation in its incidence.
 5. Forty-one cases have been clinically and hæmatologically studied.
 6. A simple and practical classification has been proposed, which is of value in applying the specific line of treatment.
 7. The macrocytic hyperchromic type is common. In the present series of 41 cases, 27 cases were macrocytic hyperchromic (65.8 per cent).
 8. The macrocytic group is identical with tropical macrocytic anæmia, as described by Napier, and is characterized by high mean corpuscular volume of over 90 c.µ. and high mean corpuscular hæmoglobin of over 30 γγ, a positive indirect van den Bergh reaction, the presence of urobilin in the urine in some cases, low leucocyte count, and free hydrochloric acid in the gastric secretion.
 9. The relation of 'toxæmia' with anæmia of pregnancy is discussed.
 10. The term 'anæmia (or anæmias) in pregnancy' is preferable to 'anæmia of pregnancy'.
- We take this opportunity of expressing our thanks to Licut.-Colonel J. C. Bharucha, I.M.S., and Dr. U. F. M. Morton, W.M.S., Principals of the Men's and Women's Medical Schools, respectively, for the facilities provided and encouragement and help given for carrying out

[Note.—In this very valuable contribution to the study of anæmia in pregnancy, there are a few points that seem to invite comment.

The statement that there were no helminthic infections in a series of 41 lower middle-class patients in India is hard to believe, although it is very probable that hookworm infection is a negligible factor as a cause of anæmia in this part of India.

It is a pity that in the age and parity graphs the writers have not given the figures for non-anæmic pregnant women, more particularly as they have exploded fallacies regarding the caste and seasonal distribution by this very means.

The writers say that this anæmia is probably due to a food deficiency and is therefore unlikely to be seasonal, as other workers have suggested. They are in the first place prejudging the case: it is from the epidemiological data that we hope to discover the ætiology of the disease and not *vice versa*. Secondly, it is quite conceivable that a variation in the seasonal incidence might be correlated with a variation in the food substances available at different seasons. Finally, Dr. Chatterjee (below) has shown that in Calcutta there is a seasonal variation in the percentage incidence of anæmia amongst pregnant women.

Early in the paper they dismiss malaria as a possible ætiological factor, but later they say that 15 out of 27 of their macrocytic cases had enlarged spleen and five gave histories suggesting chronic malaria. They do not explain the splenic enlargement in the other cases. We do not know whether the population from which their cases were drawn is a malaria-infected one, but if they had come from either Bengal or Assam, both very malarious provinces, we should not dismiss so lightly a 56 per cent incidence of enlarged spleen.—
Eaton, I. M. G.]

SOME CLINICAL ASPECTS OF ANÆMIA IN PREGNANCY IN INDIAN WOMEN LIVING IN BENGAL*

By HEMENDRA NATH CHATTERJEE, M.B.

Durbhanga Research Scholar, Calcutta University

In the present paper some of the outstanding clinical aspects of this condition are given.

Age incidence.—This was determined in 53 cases. The results are given in table I.

TABLE I

Age incidence of pregnancy anæmia

	Cases	Percentage
Below 20 years ..	8	15
20 to 29 " ..	36	68
30 to 39 " ..	8	15
40 and over " ..	1	2
	<hr/> 53	<hr/> 100

The great majority of cases belong to the second group, that is, between 20 to 29 years. The minimum age incidence is 16 years (3 cases) and maximum 40 years (1 case).

Race and caste distribution

This is shown in table II.

TABLE II

Race and caste distribution

	Cases of present series	Total admissions in 1935
Bengalee Hindu ..	47	19,143
Hindusthani Hindu ..	1	
Bengalee Mohammedan ..	2	1,900
Hindusthani Mohammedan ..	3	
Indian Christian ..	1	

The remarkably small number of Bengalee Mohammedans in our series can be accounted for by the fact that this community follows the *purdah* system more strictly and consequently the number of female members of their community who seek hospital aid is much less than that of the Hindu community.

Relation of the period of pregnancy to anæmia

The month of past attendance is shown below :—

TABLE III

	All cases	Macrocytic cases
3rd month ..	1	1
4th " ..	2	0
5th " ..	4	2
6th " ..	5	2
7th " ..	5	2
8th " ..	8	2
9th " ..	15	13
	<hr/> 40	<hr/> 22

As many of the cases sought medical advice after the anæmia was fairly advanced, it is not possible to say when the anæmia actually started, but the above figures show that anæmia can start before the third month of pregnancy and that many of the cases carry on up to or nearly up to the ninth month.

Relation of the period of pregnancy to the type of anæmia

There does not seem to be any relation between the type of anæmia and month of pregnancy. Thus, macrocytic anæmias have been found in practically all months of pregnancy from the third month onwards.

The microcytic and normocytic anæmias have also been observed in all the different months from the fourth onwards. Inasmuch as the macrocytic anæmia denotes a severe type of

subjects belonged to all the four groups as follows :—

TABLE IV
Showing incidence of the blood groups

		Percentage
Group A ..	6	18
" B ..	18	53
" AB ..	2	6
" O ..	8	23
	34	100

The table shows that there is not much relationship between any particular group and pregnancy anæmia, although patients belonging to group B were the most numerous.

Matching of infant's blood with that of the mother.—This was done only in 5 cases. In

CHART I

Percentage of pregnancy anæmia cases amongst obstetric admissions for 5 years.

hæmatological condition, the occurrence of this type of anæmia in the earlier months of pregnancy indicates that the progress of anæmia must have been rapid in these cases.

Relation of number of pregnancies to anæmia.—In our series of cases, the history in 50 cases could be obtained with certainty. The figures obtained show that the anæmia does not seem to have any relationship to the number of pregnancies excepting that it is more liable to occur in the earlier pregnancies.

1st pregnancy ..	10 cases
2nd " ..	7 "
3rd " ..	10 "
4th " ..	9 "
5th " ..	7 "
6th " ..	3 "
7th " ..	1 case
8th " ..	1 "
10th " ..	1 "
13th " ..	1 "
50 cases	

Blood groups.—The blood grouping was studied in 34 cases and it was found that the

all these cases the mother's corpuscles were found to be quite compatible with the infant's serum and *vice versa*.

Temperature in pregnancy anæmia.—The great majority of patients exhibit a febrile temperature, which is irregular and intermittent before confinement. Thus, out of 53 cases, only 5 exhibited an afebrile temperature, or a slight rise which could be neglected.

There was enlargement of the spleen in 6 cases only, in only one of which malarial parasites (malignant tertian rings) were found. The aldehyde test for kala-azar was negative in all these cases.

Excepting the case in which the malarial parasite was found other signs of malarial infection, such as rigor, chill and sweats, were absent. There was an exception in some cases in which rigor and a high rise of temperature followed intravenous injection of glucose, which however was controlled by itself. This irregular and intermittent febrile temperature which is present in the majority of cases suggests a chronic underlying infection. This is further

borne out by the fact that, in the majority of cases, the tendency to febrile temperature persists after confinement. In our series of 50 cases there was some rise of temperature in 45 cases, lasting more than a day.

A typical temperature chart is given.

As regards the treatment of the febrile condition the temperature both before and during the puerperium can usually be controlled by

Œdema.—Œdema was present in 45 out of 53 cases. General anasæra was present in as many as 20 cases, amongst which marked albuminuria was found only in two cases without, however, any casts; in the rest albumin was either absent or present only as a trace. The red blood counts of the 7 patients without œdema averaged 1.98 millions (from 3.0 to 0.89 millions), two being below one million.

Temperature chart. A typical chart in pregnancy anæmia.

glucose (20 c.cm.) intravenously every day or every alternate day either alone or along with urotropin (5 c.cm.).

CHART II
1930

Percentage incidence of anæmia.

The fever and leucocytosis.—There was leucocytosis immediately before and during the febrile attack in the majority of cases. In a few severe cases there was an absence of leucocytosis.

The urinary output in pregnancy anæmia.—One of the associated conditions of pregnancy anæmia is the diminution in the quantity of

CHART III
1931

Percentage incidence of anæmia.

urine. In the great majority of cases (36) this occurred, however, without any casts or albuminuria, or with albumin as a faint trace only.

In 4 cases there was noticeable albumin but no casts.

Complications.—The tendency to develop underlying sepsis has already been dwelt upon; the resulting febrile reaction has been mentioned previously, as also have the œdema, oliguria, and albuminuria. Lung complications including congestion and broncho-pneumonia occurred in 15 cases. There was cardiac distress with hæmic murmurs in 14 cases. Two patients died of acute endocarditis after confinement.

Diarrhœa occurred in 10 and vomiting in 5 cases.

Syphilis and anæmia of pregnancy.—In this series the serological tests for syphilis including

CHART IV
1932

Percentage incidence of anæmia.

the Wassermann reaction were performed in 15 cases; all were entirely negative.

Some other aspects of pregnancy anæmia.—There was a history of previous eclampsia in 3 cases, and of anæmic conditions during a previous pregnancy in 2 cases.

A history of hæmorrhage during the current pregnancy was obtained in 2 cases. Malarial parasite was found in one case only.

Maternal mortality.—Six patients (or 12 per cent) died in the hospital, five of these were of the macrocytic and hyperchromic type and had febrile reactions and other complications after confinement. All of them had severe degrees of anæmia, from 0.5 to 1.01 million red cells.

The sixth case was microcytic and normochromic and had a cell count of 1.8 millions.

Infantile mortality.—In 14 cases (or 28 per cent), the infants died in the hospital; 3 (6 per cent) being cases of premature or macerated babies, and in 11 cases the babies died within a few days of birth.

Of the mothers giving birth to dead infants two were macrocytic and one normocytic.

The seasonal variation of pregnancy anæmia.—The study of the seasonal variation of pregnancy anæmia in Bengal presents definite findings. The figures are obtained from two of the biggest maternity hospitals in Bengal, viz, Carmichael Medical College and Chittaranjan Seva Sadan; both show that there is a

CHART V
1933

Percentage incidence of anæmia.

definite relationship between the onset of the rains and the number of pregnancy anæmia cases.

The cases begin to come in by June and July and then the number continues to get higher, reaching the highest point in the month of September; the number remains fairly constant up to December when it again falls and the cases become very few in February, March and April. Owing to the possible fallacies due to the greater number of obstetric cases in later months of the year, the percentages of anæmia cases in both the hospitals are given in the following charts. Chart I shows the percentage of anæmia of pregnancy cases of the total cases of pregnancy for 5 years (from 1930 to 1934), and charts II to VI show this for each of these years.

Bacteriology of the stools.—We examined the stools of 20 cases of pregnancy anaemia both by the aerobic and anaerobic methods. The results may be briefly put down as follows:—

- (1) No constant bacillus or coccus was obtained excepting *Bacillus coli*. The streptococci isolated from the stools of some of them were mostly non-haemolytic. The haemolytic streptococci were present in only 5 cases. The strains of *B. coli* were generally of the non-haemolytic variety except in 6 cases in which they were haemolytic.
- (2) No constant anaerobic spore-forming organisms were found; the media used for primary culture was cooked meat and sheep's brain media. The organisms were isolated by plating

CHART VI
1934

Percentage incidence of anaemia.

and culturing them under anaerobic conditions in the Macintosh and Field's jar. The organisms were identified by the changes observed in cooked meat, milk, and the different sugars. The following results were obtained:—

<i>Clostridium welchii</i>	.. 4 cases
" <i>histolytica</i>	.. 1 case
" <i>sporogenes</i>	.. 1 "
" <i>chauveii</i>	.. 1 "
Unidentified spore-formers	.. 2 cases

(Continued at foot of next column)

THE INCIDENCE OF RHEUMATIC INFECTION IN INDIA

(AS JUDGED BY THE ADMISSION AND POST-MORTEM RATES AND BY THE CLINICAL EXPERIENCE OF TEACHING PHYSICIANS AT THE MEDICAL COLLEGES AND SCHOOLS OF INDIA): PART II

By H. STOTT, M.D., F.R.C.P., D.P.H.
LIEUTENANT-COLONEL, I.M.S.

Professor of Pathology and Physician, King George's Medical College, Lucknow, and Dean of the Medical Faculty, Lucknow University

To help forward the knowledge of the distribution of rheumatic infection in India, I have analysed the incidence of rheumatic infection as compared with the total medical admissions at King George's Medical College, Lucknow, for the past seven years 1930-1936, and also the rheumatic post-mortem rates since 1914, in the tables which follow. The physicians attached to King George's Hospital have also been good enough to furnish a note of their independent opinion—without having seen the statistical results.

ADMISSIONS FOR ACUTE AND FOR SUBACUTE RHEUMATIC INFECTION

1. Type incidence

Of the 76 admissions for acute rheumatic infection (see table I) in King George's Hospital, the admission rate for 1,000 medical admissions works out at 6. Of these admissions 32 or 42 per cent were for acute rheumatic fever (poly-synovitis), 39 or 52 per cent were for acute carditis, and 6 per cent were for chorea. A few examples of rheumatic nodules were observed amongst the polysynovitis and carditis groups. Some 4 or 5 cases of typical erythema nodosum have been observed by Dr. T. Bahadur, physician in charge of skin out-patients, during the past 10 years.

Annual incidence

The total annual medical admissions and the admission rate per 1,000 for acute rheumatic infection did not vary much from year to year.

(Continued from previous column)

The above results show the absence of any constant bacteria by the methods used by us. Gastric analyses.—In our own series gastric analyses were done in 15 cases; of these, low acidity curves were obtained only in 4 cases. Acknowledgments.—The writer wishes to express his thanks to Professor C. C. Basu, to Lieut.-Colonel P. Fleming Gow, to Principal M. N. Bose, to the visiting physicians and surgeons of the Carmichael Medical College and Chittaranjan Seva Sadan, to Dr. S. M. Ghosh, Dr. Brajendra Mahalanobis and Mr. P. C. Chakraborty.

TABLE I
Showing the admission rate per 1,000 medical admissions

Years	Poly-synovitis	CARDITIS		Chorea only	Total acute rheumatic infection	Total medical admissions	Acute rheumatic infection per 1,000 admissions
		Endo-carditis	Peri-carditis				
1930 to 1936 ..	32	25	14	5	76	13,902	6
Average per year	4.5	3.5	2	0.7	11	1,986	6

The actual figures for the successive seven years are shown in table II.

TABLE II
Showing the general medical admissions and the rheumatic infection rate

Years	General medical: total	Acute rheumatic infection per 1,000 admissions
1930	1,835	4
1931	1,981	1
1932	1,688	2
1933	2,072	11
1934	2,162	5
1935	2,154	6
1936	2,010	5

The year 1932 in Lucknow was one of phenomenal floods.

Monthly incidence.—The distribution of these acute rheumatic admissions for the seven years, according to the month of admission, is shown in table III.

TABLE III

Months	Acute rheumatic infection admissions	Climate	Average
April ..	6	Hot dry months	5
May ..	5		
June ..	4		
July ..	9		
August ..	6	Hot damp months	6.25
September ..	5		
October ..	5		
November ..	7		
December ..	6	Cold dry months (Christmas rains).	7.2
January ..	7		
February ..	7		
March ..	9		
TOTAL ..	76		

As might be expected* the lowest average monthly admissions (5) were during the hot dry months, the intermediate admissions (6) during the hot damp monsoon months, and the highest figure (7) for the cold dry months—during

*[It is not justifiable to base any conclusions on these very slight differences in seasonal incidence.—EDITOR, I. M. G.]

which there is often a break of 7 to 10 days' rain about Christmas. It is perhaps surprising that the highest figure is not recorded in the hot damp monsoon months when of course the rainfall is very heavy throughout and the chill liability high.

Age incidence.—The age distribution of the admissions for acute rheumatic infection is shown in table IV.

TABLE IV

Age, years	Fever and poly-synovitis	Carditis	Chorea	Total	Per cent
0 to 5	0	0	0	0	0
5 to 10	1	4	0	5	7
10 to 15	8	14	0	22	29
15 to 20	9	5	2	16	21
20 to 25	3	4	1	8	11
25 to 30	4	2	1	7	9
30 to 35	2	6	1	9	12
35 to 40	3	4	0	7	9
40 to 45	1	0	0	1	1
45 to 50	1	0	0	1	1
50 to 55	0	0	0	0	0
TOTAL	32	39	5	76	100

Fifty-seven per cent of the acute cases were admitted under 20 years of age, 77 per cent under 30, and 98 per cent under 40.

Sex distribution.—Of the acute rheumatic infection cases 54 were males and 19 females, whilst of the 5 chorea cases 3 were males and 2 females, but no importance can be attached to these sex distribution figures.

ADMISSION FOR CHRONIC RHEUMATIC MITRAL DISEASE

Type incidence.—Table V shows the admission rates per 1,000 medical admissions. About one-half of the chronic mitral disease admissions were without heart failure and about one-half were with heart failure. In the former group, the valve defect was predominantly stenosis in 34 per cent, regurgitation and stenosis in 37 per cent, and regurgitation only in 19 per cent. In the heart failure group 61 per cent was for congestive failure only, 18 per cent for congestive failure with auricular fibrillation, and 21 per cent for auricular fibrillation only.

TABLE V

1930 to 1936	WITHOUT HEART FAILURE				WITH HEART FAILURE AND AURICULAR FIBRILLATION				Grand total	Per mille medical admissions
	Pre-dominant stenosis	Combined S. and R.	Regurgitation only	Total	Congestive only	Congestive + A. F.	Auricular fibrillation only	Total		
Actuals ..	40	54	22	116	70	21	24	115	231	17
Per cent ..	34	37	19	..	61	18	21
Average per year	6	8	3	17	10	3	3	16	33	17

I am informed that in London at St. Bartholomew's Hospital, St. Thomas Hospital and the London Hospital the admissions due to rheumatic fever provide about 20 per mille of the whole admissions, but possibly a large number of rheumatic heart cases are sent to special hospitals. If the 6 admissions per mille for acute rheumatic infection be added to the 17 admissions per mille for chronic rheumatic valvular disease, and if allowance be made for the tropical diseases admitted to King George's Hospital, Lucknow (tropical diseases form about 10 per cent of the Lucknow medical admissions), the Lucknow rates are certainly comparable with those of London hospitals. I am, however, uncertain whether the London rates are calculated on medical admissions only or on the total admission figures. The per mille admission rates in Lucknow for each of the past seven years from 1930 have been 11, 6, 10, 19, 25, 27 and 14, respectively.

Monthly incidence.—The admissions of these heart failure cases from primary chronic mitral valve disease show an even distribution throughout the months of the year.

Age incidence.—The age distribution of the admissions for heart failure from primary chronic mitral valve disease is set out in table VI.

TABLE VI

Years	Heart failure cases	Per cent	
0 to 5	3	1	14
5 to 10	11	5	
10 to 15	18	8	
15 to 20	32	15	49
20 to 25	36	17	
25 to 30	36	17	
30 to 35	28	13	30
35 to 40	19	9	
40 to 45	17	8	
45 to 50	11	5	7
50 to 55	5	2	
TOTAL	216	100	

Fourteen per cent of the heart failure cases were under 15 years of age, 63 per cent under 30, 85 per cent under 40 and 93 per cent under 45 years of age. If a comparison be made with table IV which sets out the age of onset of

acute infection, it will be noted, whereas the incidence of 57 per cent of acute cases is under 20 and the main incidence (acute cases) is between 10 and 15 years of age, that 56 per cent of the chronic heart failures following therefrom are between 25 and 40 and that the main incidence falls between 20 and 30 as might be expected.

Sex distribution.—Of the 231 chronic rheumatic heart failure cases, 159 were in males and 72 in females, but again no deduction can be made from the sex distribution figures.

POST-MORTEM RATES

In September 1937 I reviewed the post-mortem records of King George's Medical College, Lucknow; out of a total of 661 post-mortem examinations since 1914, there was no case of acute rheumatic infection, but in 15 there was chronic rheumatic mitral disease, an incidence of 2.2 per cent; in ten of these cases there was congestive heart failure.

In 3 cases there was evidence of regurgitation only and in 12 the lesions were stenotic.

Previous rheumatic history.—In 12 (80 per cent) there was a history of previous rheumatism.

Sex and caste distribution.—Thirteen were males and two females. Thirteen were Hindus and two Mohammedans.

The age distribution at death.—All died between the ages of 5 and 46, and 60 per cent were between 15 and 30 years. One was between 5 and 10 years; one between 10 and 15 years, three between 15 and 20 years, three between 20 and 25 years and three between 25 and 30 years, one between 30 and 35 years, one between 35 and 40 years, and two were aged 45 years.

THE CLINICAL EXPERIENCE OF ATTACHED PHYSICIANS

The physicians attached to King George's Hospital have kindly recorded their independent opinions, which now follow—along with my own views which have already been published elsewhere. In the present state of our knowledge the experience of individual teaching physicians is probably of higher value than the statistical evidence available even from the most reliable sources.

Major Alexander, M.B., M.R.C.P., lately Additional Professor of Medicine, Madras, and now Professor of Medicine, King George's Medical College, Lucknow, writes :

'That rheumatism has come to be regarded as a new disease in India is difficult to explain. Rheumatism and its sequelæ are commonplace both in Madras and in the United Provinces.

In Madras acute rheumatic fever with the typical arthritis and fever yielding to salicylates and at times producing carditis occurs quite frequently, while mitral stenosis is common. That mitral stenosis can be regarded as a true index of previous rheumatism few would, I think, deny. I met with no cases of subacute rheumatism while in Madras, but most of such cases do not reach the hospital in India owing to the mildness of the disease. One case of chorea was seen by me in two years.

In Lucknow, I am under the impression that rheumatic infection is even commoner than in Madras. In the medical wards of the King George's Hospital, it is rare not to find two or three cases of chronic heart damage produced by antecedent rheumatism. In the past year, there have been two cases showing typical rheumatic nodules, pericarditis and articular pains, four cases of rheumatic chorea in children, besides certain cases where subacute rheumatism has been suspected in children. It is possible to obtain suggestive histories of previous rheumatism in the majority of cases coming to hospital with mitral stenosis'.

Dr. B. N. Vyas, M.B., Physician to King George's Hospital, writes :

'During 39 years of my practice, I cannot recall more than a dozen or so typical cases of rheumatic fever in my private practice, so that the incidence of this disease can only be described as rarer in the United Provinces. The main features of the cases which I can recall from my own practice were continued and prolonged fever, polyarthritis, and acute endocarditis. On the other hand, there are a fairly large number of cases which one comes across of valvular disease of the heart among adult boys and girls which could not have been due to any other cause than rheumatic fever in some form or other. The previous history of these cases in the majority of cases is very vague though some cases do give a definite history of arthritis. Judging therefore from my personal experience, I can only come to the conclusion that rheumatic fever does occur but is not of frequent occurrence, that the clinical syndrome in the majority of these cases is not exactly of the type described in European textbooks, and also that even a very mild form of the disease can be complicated by endocarditis followed by valvular disease of the heart, particularly mitral stenosis'.

Dr. Hargovind Sahai, Out-patient Physician and Physician to King George's Hospital, writes :

'It is a false notion that rheumatic fever is rare or unknown in India, though it is a fact that most of the cases during the acute stage do not come under our observation for certain reasons applicable to the particular disease and other diseases of acute onset. On the other hand, chronic cases with heart and joint complication can be seen almost every day in medical wards, out-patients and private practice alike. In fact a larger proportion of the cases treated by us for heart failure turn out to be rheumatic in nature when the history is carefully taken. The onset of the disease can be traced to some distant date with typical symptoms of rheumatic fever, i.e., fever, shivering, restlessness, pain in joints, profuse sweating, etc. The history of such relapses is also available in many of them.

Such cases are seen all throughout the year, but acute cases are most commonly met with during the months of December, January and February, especially at the time of the winter rains, and the history of exposure is available in almost all of them. The acute cases almost invariably are found in young adults and children, more in boys than in girls, which may be due to the fact that girls visit the hospital in fewer numbers than boys.

The tendency of this disease to recur in active form after a quiescent stage is noticeable in a fairly large number of them during the damp months. Polyarthritis is the commonest condition which gives a clue to the true nature of the disease and acute endocarditis is recognized later on in some cases. The mitral valve is most commonly affected.

Chorea and rheumatic nodules though not unknown are seen rarely as symptoms of rheumatic fever in this part of the country'.

Dr. Abdul Hameed, M.D., M.R.C.P., Physician, King George's Hospital, writes :

'The prevalence of rheumatic disease in this province is not uncommon. In my practice I have come across so far an average of one case of rheumatic disease every two months. These cases do not, as a rule, belong to Lucknow, but they come from distant places in the province. I have seen genuine cases of rheumatic fever with the fleeting type of polyarthritis, definitely yielding to salicylates. I have followed some of these cases, both in private practice and in the hospital practice, and seen definite heart lesions coming up in them later. In one case under me in the wards, it was followed by mitral and subsequently by aortic disease. All these cases were young men between the ages of 12 and 25 years and were unequivocal cases of rheumatic disease of the heart. I have seen, in practice, the following manifestations of rheumatic fever :—

(1) Acute rheumatic fever with polyarthritis—definitely yielding to salicylates and followed by heart lesions—several cases.

(2) Acute endocarditis—two cases.

(3) Mitral stenosis—simple and compensated, and with various complications—numerous cases.

(4) Rheumatic nodules—two or three cases.

(5) Chorea—two or three cases.

At the present moment, I have three cases of rheumatic heart disease under my treatment in private practice.

The above account is based on observations made on Indian patients only.

Dr. B. B. Bharia, M.D., M.R.C.P. (Lond.), writes (11-9-1937):

'During the last thirteen years that I have been in practice, I had several occasions to work in the wards and out-patients of the King George's Hospital. During this period I have seen a large number of cases of undoubted rheumatic heart disease, mostly of the chronic valvular type, but in a few of these only could I get an antecedent history of acute rheumatic fever accompanied by polyarthritis. During the same period I have only seen 6 cases of acute rheumatic fever, 4 of chorea, and 2 of rheumatic nodules. In my opinion, rheumatic infection is not at all uncommon in these provinces, but I do feel that the clinical picture produced in Indians is different from that met with in England. Rheumatic infection seems to affect Indians in a more insidious and subacute manner; nervous manifestations (chorea) are proportionately much less compared to cardiac involvement. Similarly, rheumatic nodules are very rarely seen, and I have not seen a single instance of rheumatic pleurisy. The only history of rheumatism which I could obtain from cases of chronic valvular disease was that of having suffered in the past from vague pains and aches and occasional arthralgia'.

SUMMARY

1. The incidence of acute and chronic rheumatic infection at King George's Medical College Hospital, Lucknow, has been worked out per mille medical admissions according to the clinical type, and according to seasons, age and sex.

2. The post-mortem rate for heart failure from primary mitral valve disease at Lucknow is 2.2 per cent for 661 total post-mortem examinations; 60 per cent of these cases died between 16 and 30 years of age.

3. The clinical experience of the five teaching physicians attached to King George's Hospital is given.

APPENDIX*

Note on the juvenile type of rheumatism in Bengal

By E. H. VERE HODGE, M.D., F.R.C.P.

LIEUTENANT-COLONEL, I.M.S.

Professor of Medicine, Medical College, Calcutta

Of late years interest has been focussed on the incidence of juvenile rheumatism in India,

* This note was prepared at the suggestion of Colonel Stott and forwarded to us direct.—Editor, J. M. G.

an interest which has been further stimulated by statements in European medical journals to the effect that rheumatic infection is unknown in the tropics. Reference to current medical literature in India will reveal the fact that physicians are not only familiar with the disease but that it is prevalent and an important cause of cardiac disability. During the last six years, there were 261 admissions for juvenile rheumatism to the Medical College, Calcutta. The number of admissions is given advisedly rather than the number of cases, as it is impossible to exclude sundry readmissions from the series. The number was made up as follows:—

Acute arthritis with or without cardiac lesions	54
Chorea	4
Cardiac lesion of the rheumatic type without arthritis on admission	203

In a series of 48 cases of acute arthritis, 47 patients responded to salicylates and one died of acute cardiac complications.

There appear to be certain marked differences in the Indian type from the standard European. Firstly, it would appear that the age incidence is somewhat extended. In a series of cases collected over a period of five years, the age on admission was as follows:—

Under 2 years	1
From 2 to 5 years	2
From 5 to 10 years	6
From 10 to 20	26
Above 20	15

These figures naturally do not represent the exact age of onset; in many cases it is difficult or impossible to estimate this owing to the insidious invasion of the disease. My experience shows, however, that it is not exceptional to encounter patients suffering from a first attack of rheumatic fever at the age of thirty.

As regards the age incidence of cardiac lesions, the earliest case of well-marked mitral stenosis was at four years.

Nodules are of extreme rarity. I have met this condition three times and in all three was the infection of a grave type, two rapidly succumbing to heart failure.

Chorea in Indian children in Bengal is also of extreme rarity. I have seen it in one case only, outside the hospital, though four admissions have been reported within the last six years. Among Anglo-Indian children living in congested areas it is less rare, though by no means as common as other rheumatic manifestations.

Skin eruptions I have seen in one case only, an English child domiciled in Calcutta who developed a second attack of acute rheumatism at a hill school and ultimately died of heart failure after a series of anginal attacks.

The disease is not confined to the poorer classes, but seems to depend more on surroundings, being prevalent in the congested areas of large cities. Among European children in better

SHORT NOTE ON AN EPIDEMIC OF CHICKEN-POX IN THE CENTRAL JAIL, CANNANORE

By P. V. KARAMCHANDANI, M.B., B.S.,

F.R.C.P. (Edin.)

MAJOR, I.M.S.

Superintendent, Central Jail, Cannanore

My excuse for publishing this paper on an epidemic which is all too common is some of its significant features, which in my opinion need stressing and which are so well depicted herein; and the present-day tendency to ignore the infectious nature of this disease in adults (not only by lay authorities but also by some medical men).

The epidemic started on the 5th November, 1937. The total convict population of this jail

(Continued from previous page)

circumstances who live away from the bazaar area, it is practically unknown.

Geologically, the whole of Eastern Bengal would appear to be particularly suited to the development of arthritic disorders, as the soil is entirely alluvial and the surface water level in the rainy season approximates to that of the ground level.

The range of temperature in Calcutta together with the humidity is shown in the table at the foot of the page.

A juvenile type of rheumatoid arthritis, not common but still admitted sufficiently frequently to be regarded as a definite type, is worthy of comment. These cases resemble in some essentials acute rheumatic infection and are sometimes confused with it. There is the same high fever, severe joint pains and swelling. Further, there is a tendency to develop slight relative mitral incompetence from toxic myocarditis and a progressive anæmia. The distinction, however, lies in the following characteristics:—The pain and swelling tends to persist in the joints attacked, there is a tendency to marked affection of the joints of the hands, there is no response to salicylates, true valvular lesions do not develop and there is a more definite leucocytosis. The last case admitted of this type reacted well to Prontosil.

Monthly average of temperature and humidity at Alipore (Calcutta)

Months	Average mean temperature (in °F.)	Average maximum temperature (in °F.)	Average minimum temperature (in °F.)	Mean relative humidity (in percentage)	Mean absolute humidity (in inches of mercury)
January	64.8	77.3	55.5	73	0.433
February	69.3	82.0	60.0	69	0.481
March	78.5	90.9	69.3	68	0.642
April	84.2	95.6	75.7	71	0.808
May	85.8	94.5	77.5	74	0.899
June	84.9	91.5	78.8	81	0.966
July	83.6	88.4	78.6	85	0.974
August	83.0	87.6	78.4	86	0.969
September	82.6	88.0	78.0	86	0.949
October	79.8	87.2	74.3	82	0.825
November	72.0	82.0	64.3	76	0.582
December	64.4	77.0	56.0	72	0.422

at the time was 878. The usual period of quarantine for the new-comer is 10 days. During this period the convict receives preventive vaccine against enteric and cholera, is vaccinated, and gets Foster's bowel disinfectant treatment, as a routine. Since the first case occurred in a convict who had been in jail for 12 months, the disease was apparently imported by some intermediary. Steps were taken immediately and the whole block was completely isolated, while the patient was removed to a segregation shed outside the hospital.

Details of cases are reproduced below in tabular form:—

TABLE I

Total cases	Cases with dates	Distribution by blocks
Batch no. 1	2 on 5-11-37	Borstal block 12
13 cases	8 on 6-11-37	Sixth block 1
Fever average	1 on 8-11-37	—
4 days.	1 on 10-11-37	13
	1 on 11-11-37	—

13

Then there was no case for 7 days.

Batch no. 2	5 on 19-11-37	Borstal block 22
28 cases	4 on 20-11-37	Sixth block 5
Fever average	5 on 21-11-37	Second block 1
4.1 days.	5 on 22-11-37	—
	1 on 23-11-37	28
	3 on 24-11-37	—
	1 on 26-11-37	—
	2 on 27-11-37	—
	1 on 28-11-37	—
	1 on 29-11-37	—

28

Then there was no case for 5 days.

Batch no. 3	1 on 5-12-37	Borstal block 5
7 cases	3 on 7-12-37	Sixth block 1
Fever average	2 on 9-12-37	Ninth block 1
5 days.	1 on 11-12-37	—

7

Then there was no case for 12 days.

TOTAL .. 52

All the cases were quite severe with lesions varying between 100 to 1,000 in number and temperature ranging up to 103°F. The prevalence of smallpox in the neighbourhood raised an alarm of smallpox within the jail, but there was not even a shadow of doubt about the disease being chicken-pox.

The unmistakable signs of the chicken-pox lesion, viz, centripetal distribution and want of shottiness, prove true in every case of chicken-pox and never occur in smallpox. But unilocular vesicles, successive cropping of vesicles, in the absence of umbilication have been observed in smallpox.

In spite of complete isolation of the infected cases and their contacts, the epidemic extended to 6 blocks and lasted for 82 days. Most of the European textbooks call chicken-pox 'an affection of middle childhood, being uncommon after 10 years'. This fact may have contributed to the strengthening of the prevalent belief which I have mentioned in the beginning of this paper, but which was clearly negative in this epidemic at least (*vide* age incidence, table II).

Finally, the periods of quiescence extending up to 15 days are a significant warning, neither to be too jubilant about the subsidence of the epidemic nor to be too hasty in revoking the measures of prophylaxis. Ten days being the limit laid down by the authorities for submission of infectious disease reports, these had to be discontinued four times and recommenced three times. On each occasion I was pressed by my staff to relax the measures of prophylaxis, but I was adamant, which action was justified by subsequent happenings.

Xylol was tried as a prophylactic measure with negative results.

I have to thank Lieutenant-Colonel S. C. Contractor, I.M.S., Inspector-General of Prisons, Madras, for kind permission to publish this paper.

A CASE OF ADRENAL INSUFFICIENCY SIMULATING THE ADAMS-STOKES SYNDROME

By E. SELBY PHIPSON, C.I.E., D.S.O., M.D., M.R.C.P.
COLONEL, I.M.S.

*Inspector-General of Civil Hospitals, Assam, lately
Senior Medical Officer, Colony of Aden*

THE following case seems worthy of record, not only as an example of a comparatively rare condition, but also on account of the extreme manifestations of hypotonia and bradycardia, which for a time seriously threatened the patient's life, but which were followed by complete recovery within the space of a few weeks.

Mr. R. H., aged 27, was admitted to the European General Hospital, Aden, on 3rd March, 1937, having been disembarked, together with his wife and young child, from a Dutch steamer homeward bound from Java to Rotterdam. The history given by the ship's surgeon was that for two months past the patient had complained of being easily fatigued, and of giddiness and headache, chiefly in the occipital region. It appeared he had lived a very active life in the management of a large plantation in Java and was suffering from some degree of nervous strain, apparently as a result of certain heavy responsibilities which he has been called upon to undertake in the course of his work, which would have been a heavy burden for a much older man.

History of the case while on board the ship

On 22nd February, 1937, at 3-30 a.m., he suddenly became very ill and collapsed, with slight mental confusion, vomiting and a moderate degree of cyanosis. He had an irregular pulse of about 30 to 35 a minute. There was no evidence of heart block. The heart was enlarged slightly to the left. The patient rallied after an injection of camphor in oil and cardiazol and for about a week the symptoms improved and the pulse remained fairly regular at 45 to 60 a minute. During this period he was treated with a Dutch preparation called 'diga-lin', but the dosage could not be ascertained from the ship's surgeon's report.

On 2nd March, at 3 a.m., he had a second very severe cardiac attack with acute cardiac oppression and anxiety, cold sweat, pallor, coldness of the extremities and some right-sided facial paralysis, the pulse rate varying from 25 to 30 per minute. There was still no evidence of true heart block, but he had also considerable difficulty in articulating words. He was treated with injections of camphor in ether and camphor in oil, with hot bottles to the extremities. After this the pulse rose to 40-45, though the patient still complained of severe headache and restlessness, and by 2 p.m. he was feeling

slightly better, but his condition continued to give rise to grave anxiety until he reached Aden.

History of the case after disembarkation

On 3rd March, 1937, in response to a wireless message, I visited him on board ship on her arrival at Aden and after I had discussed the case with the surgeon and with the patient's wife, he was disembarked and removed to the European General Hospital, Aden, where he came under my care. On examination I found that he looked acutely ill and his pulse rate on admission was 48, and his blood pressure was systolic, scarcely 60 mm., and diastolic, 40 mm., of mercury. There was evidence of slight cardiac dilatation to the extent of about half an inch but the heart sounds were free from any indication of valvular disease, though they were much weaker than normal. The period of the diastolic pause was greatly increased. There was no difference in the auricular and ventricular impulse rates and there was therefore no evidence of heart block, although the symptoms had borne more than a superficial resemblance to the Adams-Stokes' syndrome, nor of myocarditis, nor, indeed, of any gross cardiac lesion, though there was some reason to believe from the patient's history that at one time the cardiac function had been impaired, possibly as a result of rheumatic infection in childhood. The conditions which the heart presented were broadly those of bradycardia (which had been extreme, according to the ship's surgeon's report) and a dangerous and sustained fall in blood pressure.

The pathological origin of these two symptoms was somewhat obscure. I had been able, after discussion with the ship's surgeon, to exclude obvious toxic causes, and, although the ship's surgeon had, as he stated, treated the patient for about a week with 'digalin' (presumably a preparation of digitalis), this form of medication certainly did not give rise to the bradycardia, as the bradycardia had preceded the digitalis medication, though it may possibly have accentuated it afterwards. I considered the low pulse rate and the low blood pressure were likely to be due less to toxic causes or to a primary cardiac condition than to some remote condition acting on the heart as a secondary manifestation of some other disease. A condition which is well recognized as a sequela of acute specific fevers and occasionally met with in tropical countries after lesser febrile complaints, malarial and otherwise, and particularly after dengue fever, and which involves temporary impairment of the adrenal function, appeared to be the underlying cause of his symptoms. The sudden development of very acute symptoms on board, following a prolonged period of what had no doubt been a state of lowered vasomotor tone, suggested a hæmorrhage into the substance of the adrenal bodies already damaged by toxic or other influences.

Progress while in hospital

This tentative view was somewhat strengthened by the patient's remarkable response to subcutaneous injections of adrenalin. The effect of this line of treatment was very striking; after 4 four-hourly injections of min. 5 of adrenalin (Parke, Davis and Co., 1:1,000) his pulse rate rose from 45 to 80 and his blood pressure from 60/40 to 110/70. This form of treatment was then experimentally suspended for 58 hours, during which time his pulse rate again dropped to between 50 and 60 and his blood pressure dropped to 90/65. This appeared to me to indicate that the adrenalin medication was doing good and that, on its temporary withdrawal, the want of it was felt. It was accordingly started again on 6th March, in somewhat smaller dosage (min. 5, *b.i.d.*). This was continued for 48 hours, when it was found that his blood pressure had risen to 130/70 and his objective symptoms and all discomfort had completely disappeared.

About this time the patient's father, mother and father-in-law who, on learning by wireless from the ship of the apparently desperate condition of the patient, had chartered a K. L. M. air liner, arrived by air from Holland, and his father suggested that, if I agreed, they would like to take him back with them to Holland by air. I replied, after careful consideration, that his progress in hospital had been so good that if he was prepared to employ the services of a doctor or a trained nurse on the voyage to continue the treatment, and was prepared to provide the patient with a supply of oxygen and a Haldane's oxygen apparatus (which I had previously ascertained, through the courtesy of my colleague, Group-Captain E. W. Craig, R.A.F.M.S., Principal Medical Officer, Aden Command, could be made available) and provided that the pilot was able and willing to limit his maximum flying altitude to 10,000 feet, I thought that the voyage could be undertaken without undue risk. It was not found possible to obtain the services of a doctor, but a lady resident in Aden, a fully-trained (London Hospital) nurse, who, before her marriage, had been on the staff at the European General Hospital, Aden, agreed to travel by air to Holland in charge of the patient. The patient's father willingly agreed to all the conditions I considered necessary to impose. In the consideration of the precautionary measures necessary I naturally sought, and was guided by, the advice of Group-Captain Craig, whose wide experience of the actual problems involved was of the greatest value, and I gratefully acknowledge his willing and courteous help.

The patient's departure by air

The K. L. M. air liner, which had been chartered by the patient's father, left Aden at day-break on 9th March, with the patient, his wife and child, the party from Holland, and the

trained nurse. The nurse had received instructions from me to continue the adrenalin medication in doses of min. 4, subcutaneously, twice a day, to administer oxygen with the Haldane's apparatus if there should be any signs of respiratory or cardiac distress, and, if necessary, to use coramine as a further cardiac and respiratory stimulant. I thought it unlikely that oxygen would actually be required, but it was plainly necessary to provide for such a contingency in transporting a patient 4,000 miles by air who had but recently suffered from severe and almost fatal cardiac crises.

The captain of the air liner, Captain Smyrnoff, had agreed to keep his flying altitude as low as possible having regard to the comfort of the passengers, and if necessary to land at the nearest air-port and abandon the idea of further transport by air, and to limit the maximum altitude to 10,000 feet. He had also made advance arrangements by cable to pick up further supplies of oxygen *en route* if necessary. I learnt later that the air liner travelled at an average altitude of 3,000 feet, and only occasionally rose to 5,000 feet. This, I believe, could only have been done by a highly-skilled pilot.

The air liner reached Cairo the same evening, Rome the following evening and reached her destination in Holland soon after 1 p.m. the next day, 11th March, with all well on board.

The nurse's report, which she sent me later, indicated that there was never any indication for the administration of oxygen or stimulants and that everything went according to plan, except that four hours after leaving Aden on arrival over Port Sudan, the hypodermic syringe was found to be broken and the injection due at 10 a.m. could not be given. This was significant, as the patient apparently felt the loss of it for, by the evening, shortly before arriving at Cairo, he felt unduly fatigued and complained of double vision, due, no doubt, to unequal loss of tone in the ocular muscles. As soon as a new syringe had been obtained and he had had his injection, however, these symptoms left him, and after a light dinner he retired early and slept well all night. The following evening, at Rome, he was able to sit up and take his evening meal in comfort in the hotel with his family, and the next day, soon after 1 p.m., he arrived at Flushing none the worse for the 4,000-mile journey, which, as far as the annals of Aden are concerned, was unique.

Discussion

I had not had the patient under observation long enough, nor sufficient resources at my disposal, to arrive at other than a tentative diagnosis. I had previously advised the patient's father to have his son examined by a cardiologist of repute in Amsterdam, to confirm my view that the condition of the heart itself was not the primary cause of the patient's alarming

symptoms, and that the true ætiological factor was probably adrenal insufficiency, temporary in character, the sequela, no doubt, of some febrile complaint contracted in Java, which, in itself, may have been of but slight importance.

The patient, soon after his return to Holland, was accordingly examined by his family doctor, Dr. L. H. J. Brongers of Meddelburg, and was then seen in consultation by Dr. de Haas, an Amsterdam consultant. The patient's father was good enough to send me the reports of these two doctors, who had seen my report on the case and who, at the time of the examination, were satisfied that there was no cardiac lesion of any kind, and that the patient was in a perfectly sound state of health, and that the condition must have been 'an acute vasomotor paralysis with secondary cardiac phenomena'. With the re-establishment of the normal vasomotor tone, which coincided with, and may have been determined by, the patient's return to temperate climate, all symptoms and signs completely disappeared.

The true ætiology of the condition presented by this case, which could not unfortunately be fully studied and which, after recovery, left apparently no traces of any morbid change, must be largely a matter of surmise. Although adrenal insufficiency appeared to be the most probable cause, there are other conditions which might have accounted for the train of symptoms described. The group of maladies, for example, which includes vasovagal syncope, the carotid sinus mechanism, and the syndromes of Gowers and of Nothnagel all resemble in certain respects the condition described, but these, judging from the only account at present accessible to me, by Sir Thomas Lewis (1932) (kindly placed at my disposal by Professor F. R. Fraser of the British Post-Graduate Medical School), are all described as being of a transient nature in the sense that their manifestations cover a period measurable in minutes, and not of many days as in the case reported.

Although the necessary clinical observations were wanting on board the ship there can be little doubt that the marked hypotension, which was observed as soon as the case was admitted to hospital, had been present throughout the attack which began on 22nd February, and which lasted, on and off, for over a week, and that therefore the underlying cause at least was capable of sustained, though possibly irregular, action. This is more suggestive of depressed activity of the adrenal medulla than of any of the conditions related to vasovagal syncope, though the co-existence of bradycardia with the hypotonia certainly suggests parasympathetic stimulation.

My excuse for recording these somewhat meagre observations must be the concluding sentences of Sir Thomas Lewis's paper referred to: '... Our understanding of the transient derangements of the circulation must depend on

A STUDY OF THE DIETARY HABITS OF SOME COMMUNITIES LIVING AT CALCUTTA

By DURGA DAS MITRA, M.B., M.Sc., D.P.H.

(From the Department of Biochemistry and Nutrition, All-India Institute of Hygiene and Public Health, Calcutta)

THE object of this investigation was to ascertain the dietary habits of different communities on a qualitative rather than a quantitative basis. The technique employed was to find out the average number of times a particular foodstuff was consumed each day in a group of individuals. For instance, suppose in a group of ten, each member takes rice once a day, the index for rice would be $\frac{10}{10} = 1$. Similarly, if only five of them took rice twice a day, the index would again be $1 \left(\frac{5 \times 2}{10} \right)$. In practice it is simpler to limit the number of foodstuffs to include similar ones under a group, e.g., carrots and potatoes under non-leafy vegetables, and meat and fish under animal foods. Milk and milk products on account of their importance should be considered alone. The method consists in giving each member a card on which he or she writes down exactly what is consumed at each meal in the day. Greater accuracy can of course be obtained if the average of several days is taken. Obviously the highest index, i.e., the maximum number of times a given food is consumed in a day, is unlikely to exceed three while the minimum may be *nil* or a small fraction. The investigator himself can arrange the foodstuffs into any suitable set after inspection of cards.

(Continued from previous page)

our directly ascertaining whether the blood pressure rises or falls, and what happens to the pulse rate. Yet these, more often than not, are just the data that are not available, and so knowledge of vasomotor seizures in man remains more obscure than it should remain.

The attendant circumstances in this case have been reported in rather more detail than is perhaps usual, in the hope that they may prove of interest to practitioners abroad who may have, from time to time, to consider the propriety of air transport of patients from tropical countries to the United Kingdom. On the main air routes this mode of transport is, no doubt, already fairly frequently made use of, but it is perhaps of value to place on record the particulars of the successful transport, 4,000 miles by air, by 3 stages in $2\frac{1}{2}$ days, of a case which, at first sight, appeared to be a highly unsatisfactory subject for air transport.

REFERENCE

Lewis, T. (1932). Vasovagal Syncope and the Carotid Sinus Mechanism. *Brit. Med. Journ.*, Vol. I, p. 873.

The method can be relatively easily applied to a school where the master can give the children full instructions as to filling in the cards. A number of foods may be marked on the cards before issue, but it is probably better to let the subjects write down exactly what they consumed, as in this way unsuspected comestibles may be discovered by the investigator. In the actual process of calculating the results, a large sheet may be prepared with the selected types of foods written up. Each card is then taken and one or more marks put opposite the item concerned. All the cards having been dealt with, the marks are summed for each group and the index obtained by dividing this figure by the number of cards.

Below is an example of how the diet cards should be filled in and it will be appreciated that the method is within the reach of an intelligent school child.

The investigation discussed here included four different communities, namely, Bengali Hindus, Moslems, Marwaris, and Anglo-Indians, and all the children belonged to a relatively well-to-do class, in the economic scale. The Moslems included both Bengali and up-country Mohammedans, but the latter were in the majority, though many of them were domiciled in Calcutta. In the analysis the comestibles were all grouped under nine heads, viz, rice, bread, pulses, vegetables, fruits, milk and milk products, fish, eggs and meat.

A few points in the analysis of these diet sheets deserve special mention. Both the Bengali Hindus and the Marwaris often record green vegetables (*sag*) as one of the usual items of their diet while they are seldom mentioned by the Mohammedans and the Anglo-Indian communities. The Anglo-Indians seem to favour jams and jellies while the Marwaris are fond of *chutnies* and condiments. The Marwaris are vegetarians, and consume no fish, flesh, or eggs.

The Marwaris usually take hand-made bread of *atta* and *papar* (made of pounded gram); the Anglo-Indians take white loaves while the Bengali Hindus often mention *luchis* which are made of white flour. In only eight out of one hundred and sixty Bengali diet sheets has brown bread been specifically mentioned.

The Mohammedans and the Anglo-Indians take pulses, vegetables and dairy products less often than the Bengali Hindus and the Marwaris. They also consume meat more often than the Bengali Hindus who however take rather more often fish and eggs. The Mohammedans take fruits and nuts less often than the other groups.

The meat mentioned in the Anglo-Indian diet sheets is most varied, e.g., beef, mutton, bacon, fowl, duck, etc. In the Mohammedan diet sheets are mentioned beef, fowl and mutton, while in the Bengali Hindu diet sheets are mentioned only goat meat and sometimes mutton and rarely fowl.

tarians, do not consume milk products more frequently than the Bengali Hindus who take fish, mutton or goat. The Anglo-Indian community

TABLE II

Showing the daily indices for the common articles of food of the different communities

COMMUNITIES	BENGALI HINDUS		MARWARIS		ALL HINDUS (INCLUDING BENGALI HINDUS AND MARWARIS)		MOHAMMEDANS		ANGLO-INDIANS	
Number of children questioned	160		100		260		200		100	
Comestibles	Number	Daily indices	Number	Daily indices	Number	Daily indices	Number	Daily indices	Number	Daily indices
1. Rice ..	254	1.6	94	0.9	348	1.3	259	1.3	140	1.4
2. Bread ..	278	1.7	224	2.2	502	1.9	383	1.9	277	2.8
3. Pulses ..	246	1.5	138	1.4	384	1.5	158	0.8	99	1.0
4. Vegetables ..	386	2.4	191	1.9	577	2.2	115	0.6	94	0.9
5. Fruits and nuts.	102	0.6	42	0.4	144	0.5	63	0.3	66	0.7
6. Milk and milk preparations.	303	1.8	106	1.1	409	1.6	146	0.7	70	0.7
7. Fish ..	220	1.4	0	0.0	220	0.8	64	0.3	14	0.1
8. Eggs ..	39	0.2	0	0.0	39	0.1	20	0.1	51	0.5
9. Meat ..	20	0.1	0	0.0	20	0.1	265	1.3	128	1.3

The Anglo-Indians have the maximum index for bread, viz, 2.8; next come the Marwaris, 2.2; while the Bengali Hindus have the maximum index for rice, viz, 1.6.

In considering animal proteins, milk and milk preparations are considered separately because the small quantity of milk that is taken by grown-up boys in an average home can hardly be considered side by side with the more concentrated protein foods, e.g., fish, eggs or meat, to which singly and as a group reference will be made in this paper.

The Anglo-Indians have the highest index for animal protein, viz, 1.9. Wilson *et al.* (1936) have also found that the total animal protein intake (29.95 grammes) per 'man value' amongst the Anglo-Indians is high in comparison to that of an average Bengali Hindu family and others.

also have a low index (0.7) for milk and milk products and their cereals consist of rice (1.4) and white bread (2.8). This community would appear to have a diet which is poor in calcium, phosphorus, and vitamins of the B group. In this respect the Marwaris are somewhat better off, as they take wheat as *atta* rather than bread made of white flour.

Conclusion

In this paper an attempt has been made to find out the number of times some common articles of food were consumed per boy per day. This has been studied in four communities, viz, Bengali Hindus, Marwaris, Mohammedans and Anglo-Indians, and shows their different habits and customs. The boys in general belong to the relatively better-off classes of their respec-

THE GUINEA-PIG IN THE LABORATORY DIAGNOSIS OF TUBERCULOSIS

By R. K. GOYAL, M.B., Ph.D., D.Sc., M.R.C.P.,
M.R.C.S., F.R.S.E.

From the Bacteriological Department, School of
Tropical Medicine, Calcutta

THE discovery of the susceptibility of the guinea-pig to mammalian tuberculosis was a landmark in the history of research. Although the latest cultural methods for the isolation of tubercle bacilli are very efficacious, yet the guinea-pig cannot be dispensed with in a laboratory engaged on tuberculosis research.

(Continued from previous page)

tive communities. The comparison has been made in terms of the 'daily index' which has been taken as the ratio of the number of times a particular item of food is consumed each day to the number of children consuming it.

Nine comestibles have been studied, viz, (i) rice, (ii) bread, (iii) pulses, (iv) vegetables, (v) fruits and nuts, (vi) milk and milk preparations, (vii) fish, (viii) eggs, and (ix) meat.

Some of the maximum indices are as follows:

Rice 1.6 (Bengali Hindus); bread 2.8 (Anglo-Indians); pulses 1.5 (Bengali Hindus); vegetables 2.4 (Bengali Hindus); fish 1.4 (Bengali Hindus); meat 1.3 (Mohammedans and Anglo-Indians).

It appears among other points that the Mohammedans and the Anglo-Indians take the pulses and vegetables less often, and meat, fish and eggs, taken together, more often than the Hindus for the reason that the Marwaris are vegetarians.

The Marwaris do not appear to compensate for their vegetarian habits by a greater frequency of consumption of milk.

The Anglo-Indians consume a diet which is poor in calcium, phosphorus and vitamins of the B group because of their taking polished rice and white flour as cereal foods.

It should be pointed out, however, that such a survey as this gives no quantitative information. A low index may mean that a particular food is consumed say only once a day but in large quantities. In general however the index does probably show the dietary trend of a community or social class.

I wish to acknowledge the help received in this inquiry from Dr. H. Ellis C. Wilson, M.B., Ch.B., D.Sc., Professor of Biochemistry and Nutrition, and to express thanks to Dr. R. B. Lal, M.B., B.S., D.P.H., D.T.M. & H., D.B., Officiating Director, All-India Institute of Hygiene and Public Health, for his kind permission for publication.

The extreme rarity of spontaneous mammalian tuberculosis in this animal led workers to believe that other strains of tubercle bacilli could not exist in a saprophytic state. Whenever suspected material was inoculated, the bacilli isolated were always considered to have been derived from the inoculum. This mistake has been and is still the cause of many fallacious conclusions.

The study of bacterial variation in the mycobacterium has given at best debatable results. Dissociation can be effected *in vivo* as well as *in vitro*. Birkhaug (1935) made an exhaustive study of the dissociation of tubercle bacilli. He had recourse to the ingenious method of Ninni in his work. Ninni (1930) had found that the best way of infecting a guinea-pig was by inoculation into its cervical lymphatic glands. Birkhaug injected his cultures into this site and was able to recover rough and smooth strains from the blood, although he had injected only rough strains. It was taken for granted that the smooth strains thus obtained had come from the injected material and not from the guinea-pig.

The serological studies of Schaefer (1935) showed clearly that the so-called smooth variants of rough mammalian bacilli belonged to the avian group. It is inconceivable that a mammalian strain could give rise to a variant of the avian group. At this stage, Saenz and his collaborators (1936) came to the conclusion that a certain number of guinea-pigs harboured a new type of tubercle bacillus. They considered it to be different from avian strains because of its feeble pathogenicity and its production of an acid reaction when grown in Sauton's medium. This contention received support from the serological studies of Schaefer (1937). He found that this bacillus differed from the typical avian bacilli in its antigenic constitution. But Goyal (1936) found that the new type of bacillus could not be differentiated from the avian on the basis of the reaction produced in the liquid media. The change in the reaction of the medium depended not only on the particular strain under examination but also on the physical conditions operating at the time, e.g., the proportion between the quantity of the bacilli and the fluid medium, the shape of the container, and the presence or absence of a surface layer. These findings were accepted by Saenz and his collaborators. The low virulence was not considered to be of especial significance, as a virulent avian strain could become non-pathogenic under unfavourable conditions. Schaefer decided later that the new type of bacillus should be classified as an avian strain.

It can be safely concluded that a certain number of apparently normal guinea-pigs harbour tubercle bacilli of the avian group.

In view of this work, it would be unscientific to consider every organism isolated from an inoculated guinea-pig as having been derived

THE SPECIFIC GRAVITY OF SERUM OF EPIDEMIC DROPSY PATIENTS

By C. L. PASRICHA,

MAJOR, I.M.S.

S. LAL,

and

K. S. MALIK

(From the Department of Bacteriology and Pathology, School of Tropical Medicine, Calcutta)

MOORE and VAN SLYKE (1930) have shown that when there is a fall of the plasma albumin below 2.5 per cent or of the total plasma protein below 5.5 per cent oedema occurs. These authors state that the serum specific gravity that corresponds to these limits of plasma protein content is 1.0227 to 1.0233. Chopra, Mukherjee, and Gupta (1935) studied the

(Continued from opposite page)

from the inoculum. Some workers would say that, if the guinea-pigs were tested with the Mantoux's test before inoculation, then there would be no difficulty, because the negative-reactors could safely be used. But the work of Saenz *et al.* has shown that this argument is fallacious. Guinea-pigs may react negatively to tuberculin at the time of the injection of a non-pathogenic inoculum, but become allergic later on. A guinea-pig giving a positive tuberculin test may not present any macroscopic lesions on autopsy; the films from the glands and spleen may not show the presence of acid-fast bacilli, but the culture of the spleen would reveal the presence of acid-fast bacilli of the avian group.

The presence of avian bacilli in the guinea-pig is rare so that if two guinea-pigs injected simultaneously with the material under examination show the presence of avian bacilli, their presence in the inoculum can be safely concluded.

The non-recognition of the presence of avian bacilli in the guinea-pig led to the postulation of the theory of the filterable form of tubercle bacillus. When the Chamberland filtrate of tubercle bacilli was injected into guinea-pigs and acid-fast bacilli occasionally found in the lymph glands, certain workers (Valtis, 1924) jumped to the conclusion that the bacilli must have come from the filtrate; they might have been present in the animals before injection.

plasma protein of epidemic dropsy patients and recorded low protein values for albumin and increase in the globulin fractions.

The present investigation was undertaken to determine the specific gravity of the serum of patients suffering from epidemic dropsy. Sera from twelve in-patients suffering from epidemic dropsy and sera from six healthy individuals were used for this work. All the patients had well-marked oedema when the first samples of serum were taken. A second sample of serum was examined in 10 patients when the oedema had entirely disappeared. The blood was collected in the morning before any heavy meal was taken by the patient. In all cases the serum obtained was clear. A pyknometer of about 1 c.cm. capacity was used for the determination of the specific gravity of the serum. The estimations were made in a cool room and necessary corrections made for variations of temperature. The results are given in tabular form.

TABLE

Showing the specific gravity of the serum of patients suffering from epidemic dropsy and the specific gravity of the serum of six healthy individuals

Number.	Serum taken when the patients had well-marked oedema	Serum taken when the oedema had entirely disappeared	Serum taken from healthy individuals
1	1.0229	1.0249	1. 1.0258
2	1.0231	1.0248	2. 1.0275
3	1.0220	1.0269	3. 1.0258
4	1.0202	1.0247	4. 1.0263
5	1.0235	1.0270	5. 1.0265
6	1.0209	1.0261	6. 1.0256
7	1.0229	1.0268	..
8	1.0216	1.0255	..
9	1.0223	1.0264	..
10	1.0235	1.0269	..
11	1.0229	1.0246	..
12	1.0140	Died.	..

It will be seen that the specific gravity of the serum of healthy individuals ranges between 1.0256 to 1.0275 with a mean value of 1.0263. The specific gravity of the serum of epidemic dropsy patients with oedema varies from 1.0140 to 1.0235 with a mean value of 1.0223. The specific gravity of 1.0140 was obtained in a patient who was very ill and at the time of examination had marked oedema. This patient died ten days later. This figure has been excluded from the determination of the mean value. When the oedema disappears the specific gravity of the serum tends to approach that of the normal serum, varying in the patients examined from 1.0246 to 1.0270 with a mean value of 1.0259.

It will be seen from these observations that the specific gravity of the serum of patients

(Continued at foot of next page)

A METHOD OF ANTI-LARVAL OILING FOR RIVERS

By D. MANSON, M.B., Ch.B., L.D.S. (Glas.)

Jorehaut Tea Company, Limited, Central Laboratory,
Cinnamara P. O., Assam

Introduction.—During the monsoon in Assam, the rainfall is characterized by spells of heavy downpour followed by intervals, short or long, of hot, dry weather. The result of this irregularly distributed rainfall is that the permanent rivers and streams sometimes flow slowly and sluggishly, and at other times, after heavy rains, are converted into wide, deep, rapidly-flowing channels loaded with silt and debris.

The velocity of these streams and rivers therefore varies considerably. In a previous article, the writer has detailed experiments dealing with these velocities. It was found that velocities exceeding 2.04 miles per hour were sufficient to wash out the larval stages of *Anopheles minimus* which is the principal, almost the only, vector of human malaria in Assam. Similar results were obtained by De Jesus in the Philippines. Where, however, there are diverticula or culs-de-sac in the river banks, and in intervals between heavy rainfalls when the velocity of the rivers and streams falls below two miles per hour, larvæ of *A. minimus* are abundantly found. During the months of December, January and February, larval breeding proceeds very slowly and larval wintering occurs. There are no periods of flush and semi-stagnation such as are characteristic of the monsoon. In the monsoon, flushing is succeeded by spells of low river velocity

(Continued from previous page)

with œdema corresponds closely to the limits suggested by Moore and Van Slyke. Œdema is present when the specific gravity is 1.0235 or lower, and when the œdema disappears the specific gravity approaches the specific gravity of the control series of healthy individuals.

The specific gravity of samples of clear œdema fluid obtained by the insertion of needles was found to be 1.0047 in the four patients examined.

Summary

The specific gravity of the serum of twelve epidemic dropsy patients are recorded. During the stage when œdema is present the specific gravity is 1.0235 or lower and when the œdema disappears the specific gravity of the serum rises to approach the specific gravity of serum of healthy individuals.

and at the beginning of these intervals fresh batches of *A. minimus* larvæ infiltrate from areas where no anti-larval control methods are in operation.

In anti-larval control areas, therefore, the regular oiling of river banks is a necessity during the monsoon months, when transmission of malaria is constant and where large bodies of labourers are employed as on tea gardens. Oiling is carried on during these spells between heavy rains when the river velocities permit the presence of *A. minimus* larvæ, and larval infiltration has occurred.

But even such velocities as two miles per hour render efficient oiling difficult. The old methods of drip oilers and ordinary spraying of river banks are not only relatively ineffective but extremely wasteful.

In this area, Jorhat-Titabar-Mariani, anti-larval control has been in operation since 1931.

Old method of oiling.—Until last year, the method of oiling moving water was as follows:—

When *A. minimus* larvæ were found along a section of the river bank, that area was enclosed with bamboos placed so as to isolate the breeding ground. Two short bamboos about 3 feet

Fig. 1.

Fig. 2.

long were placed at each end of the area at right angles to the river bank. One end of each short bamboo rested on the bank and the free ends were joined by a bamboo about 12 or 13 feet long so as to form an oblong enclosure. The diagram (figure 1) shows this clearly.

The diagram shows a section of river with a shaded *A. minimus* breeding area enclosed by bamboos. The arrows indicate the direction of flow. A second bamboo enclosure is marked 2 and is unshaded.

Oil was sprayed inside the bamboo enclosure and after an interval of 15 to 20 minutes (sufficient to allow for larval extermination when using Malariol) the lower end short bamboo marked B in the diagram was removed and the oil allowed to run into a similar enclosure in the direction of river flow. This method was effective but somewhat cumbersome and wasteful.

In order to economize still further in oil expenditure and to make the application easier

for the anti-larval gang, the method now employed is as follows:—

New method.—A length of coarse gunny with as wide a mesh as possible is selected. A piece 3 feet broad by about 15 to 20 feet long is about the regulation size used here.

To the upper side of this are attached, with rough string, strips of wood or bamboo. These are placed at intervals of 2 or 3 inches and extend across the gunny. The result forms what might be compared to a rough *chick*.

The diagram (figure 2) explains the idea clearly.

The wooden strips need not be too heavy, the lighter the better, as their sole object is to support the gunny on the water.

When completed, the gunny mat well-oiled with Malariol is now ready for use. It is rolled up and carried to the river bank. In using it, it is unrolled quickly over the larval breeding area. One long edge rests on the bank and the other is free. The top end of the mat is fastened to the river bank and, after the usual interval of 15 to 20 minutes, the mat is rolled up and used again as often as necessary.

Oil is thus easily conserved in the meshes of the gunny and one oiling is sufficient to allow the mat to be used on three or four areas with-

out replenishment. Very little oil is washed away by the action of the water in the river, as it is well retained in the gunny.

The mat is much more convenient to handle than the bamboo and one man should easily carry it round. It can be applied very quickly over the breeding areas and the amount of oil used is not more than one-half of that required by the older method of bamboo enclosure and one-quarter of that needed for drip oiling.

This method has been used during the past year with much success on all local rivers and streams where ordinary methods of oiling have formerly been wasteful and only partially successful.

Summary.—An economical and efficient method of oiling flowing water in rivers and streams in Assam has been described. The gunny mat method is cheap and the amount of oil used is considerably reduced.

A boy, aged 11 years, was bitten by a scorpion on the 19th October, 1937, when playing in the field. The scorpion was killed by his father who was near by. On the 23rd October, five days after the bite, he felt giddy and fell down, and it was found that he was unable to walk and speak, for which condition he was admitted into the Sassoon Hospital on the 4th November.

The father is definite in the history that the boy was unable to speak for the past week and unable to move the right upper and lower limbs. He also states that when drinking any fluid, it is seen to trickle out again from the right side of his mouth.

Physical examination reveals it to be a case of aphasia, with a supra-nuclear right facial paralysis and right hemiplegia. Sensations present and intact. On the right side movements and power extremely diminished in both the upper and lower limbs. Knee jerk and ankle jerk exaggerated; plantar reflex of the extensor type (Babinski); superficial abdominal and cremasteric reflexes absent.

There is no doubt that this condition has followed upon the bite of the scorpion. There is no valvular lesion in the heart and, although difficult to explain, it must be attributed to the

effect of the scorpion venom. Scorpion venom is said to resemble closely snake venom in action. Chopra, in his *Handbook of Tropical Therapeutics*, mentions that scorpion venom 'produces coagulation of blood, hæmorrhages due to injury to the capillary walls and leads to the formation of emboli due to the agglutination of the red blood corpuscles'. Amongst other effects he goes on to state, 'the nervous system becomes highly irritable, reflexes are increased, there might be a locomotor paralysis, nystagmus and even blindness'.

USE OF PROSEPTASINE IN CELLULITIS OF THE ARM

By MOHAN LAL PATHAK, M.B., B.S.
 In charge, Sub-Jail and Police Hospitals, Dharamsala,
 District Kangra

P. S., male, aged 18 years, a college student, presented himself in the Police Hospital with complaint of fever and swelling of right arm and forearm on 2nd September, 1937.

History.—Two days previously the patient had travelled a distance of about 12 miles in a hilly tract on foot, carrying a load on his back and supporting it by his bent right arm. After reaching his destination he had noticed slight swelling of the right arm and forearm. The swelling and stiffness gradually increased and the night before coming to the hospital he got fever with a slight rigor.

On examination there was nothing remarkable about the appearance of the patient. The lower half of the right arm and upper third of right forearm were

swollen, hot and tender to touch. Elbow joint seemed to be normal though movements were restricted and painful.

Treatment.—The swollen area was painted with ichthyol belladonna glycerine and the patient was advised rest and fomentations. But the swelling increased and the patient got fever with definite rigors and sweats at night. The same treatment was continued with the addition of intramuscular injection of 10 c.cm. polyvalent antistreptococcal serum.

This did not result in any improvement. If anything the condition became worse. Patient was naturally becoming anxious and every day fever and insomnia were telling on his general health. The swelling was homogeneous and not soft or pointing anywhere. A blood film showed polymorphonuclear leucocytosis. He was given five tablets of proseptasine (P-benzylamino-benzenesulphonamide). Next day the swelling was reduced by half and the patient felt much better. Another five tablets completed his recovery.

Probably the cellulitis was streptococcal in nature, but as the swelling neither discharged nor was opened, it is impossible to be sure on this point.

Summary.—A case of cellulitis of the right arm and forearm is described. It was cured with proseptasine (M. & B.). It is impossible to generalize from one case but the marvellous response to proseptasine suggests the value of this drug or other preparations of sulphonilamide in cellulitis and allied conditions.

SPINAL TUMOUR AND ITS DIAGNOSIS

By M. G. KINI, M.C., M.B., M.Ch. (Orth.), F.R.C.S.E.

Surgeon

and

P. KESAVASWAMY

Radiologist

King George Hospital, Vizagapatam (S. India)

In India all types of nervous disease exist, but very few spinal tumours are reported. This does not mean that the incidence of spinal tumours in this country is a rare phenomenon. The diagnosis of a spinal tumour is made by the clinical symptoms of (1) the root cycle usually unilateral; (2) the Brown-Séquard syndrome; (3) the compression paraplegia, and by special clinical tests such as lumbar puncture with biochemical test of the cerebro-spinal fluid, and by special types of lumbar puncture such as Quickenstedt's and Ayer's and cisterna puncture with the injection of lipiodol and radiography to localize the tumour.

A male, aged 35 years, was admitted in 1934 with a history of pain in the left side of the abdomen and inability to walk, 20 days prior to his admission to hospital. He gave no history of injury. In the beginning, for four months the pain was on the left side of the abdomen and of a stabbing nature, increased on sneezing or coughing and on bending forwards or sideways. The pain increased at night on lying down on his back and so he had to sit up in bed which gave him relief. Six months after the onset of the pain, he noticed tingling and numbness, first in the lower left extremity and ten days later in the right lower extremity. Gradually his left limb became weak with ultimate loss of power; subsequently he found his right limb was affected in the same way. Twenty days prior to his admission he found both his limbs paralysed. He had no loss of control over his urination or defæcation.

He was admitted with complete paralysis of all the muscles governing the ankle, foot, knee and hip of both the lower limbs. Epicritic and protopathic sensation was lost in both lower extremities up to the joint midway between the umbilicus and the symphysis pubis.

Fig. 1.—Showing the spinal block after lipiodol injection.

Fig. 2.—The photograph to scale showing the size of the tumour.

All the deep reflexes of the lower extremities were exaggerated; joint sense lost up to knee.

Lumbar puncture fluid showed spontaneous coagulation with 350 mg. per cent of total proteins, increased globulin and a cell count of 4 per c.mm. A cisterna puncture was done injecting 2 c.cm. of lipiodol which was found held up at the level of the 9th thoracic vertebra on radiographic examination, as shown in figure 1.

Under local anaesthesia nerve block, supplemented with general anaesthesia, the 6th, 7th and 8th laminae

were removed and a tumour situated in the postero-lateral aspect of the cord on the left side was easily removed and the wound sutured in layers.

The patient made an uneventful recovery. He recovered all sensations both epieritic and protopathic in about 40 days and when he was discharged from the hospital he was able to walk with the aid of crutches. Three years after the operation, he reported that he was able to resume his work as a farmer three months after the operation and is keeping perfectly fit.

Fig. 3.—Photomicrograph of the specimen. The section shows several large engorged thin-walled vessels, typical rosette-like arrangement of elongated oval nuclei round faintly-fibrillated faintly-staining areas. The histological structure is that of a neoplasm derived from the cells of the sheath of Schwann.

This case illustrates the root cycle syndrome with the compression paraplegia of both the limbs. The Brown-Séquard syndrome stage must have passed before admission to hospital. There was a positive Froin's syndrome. The anaesthesia affected both the limbs equally. The pathological report showed the tumour to be a meningioma.

A CASE OF STAPHYLOCOCCAL POLYARTHRITIS

By M. S. H. MODY, M.B., B.S. (Bom.), M.R.C.S. (Eng.)
L.R.C.P., D.T.M. & H. (Lond.)
Poona

STAPHYLOCOCCAL pyæmic infections are as a rule suppurative. The following case is of interest as it points to the possibility of a non-suppurative inflammation of the joints.

B., a Parsi aged 35, resident of Bombay, suddenly became ill on 22nd August, 1937, with a high temperature and severe pain in all the joints, in Poona, when on a week-end visit. There is nothing of interest in his family history, and his personal history is not of any moment.

He had, however, been a subject of severe acne and had still some comedones on his face, with one or two of them in the state of suppuration. While in England many years ago, he had been given injections of an autogenous acne vaccine.

When I examined him, I found that he had a temperature of 102°F. and on inquiry I learned that it was not ushered in with a rigor.

While all the joints were painful, only the knees, elbows and wrists were badly involved, the others allowing free movement though to some extent painful. All the systems were examined and found normal. I made a provisional diagnosis of rheumatic fever and I prescribed sodium salicylate, 90 to 100 grains *per diem*, for a period of twelve days, without any benefit. Owing to signs of intolerance, the dose was reduced to 30 grains *per diem*. This altered daily dose of 30 grains was kept on for a week, after which the drug was completely stopped, as the patient showed no improvement.

The temperature, however, continued between 100° and 103°F. with a pulse rate varying between 88 to 120 per minute. During this treatment 'Rheumatic Phylacogen' (P. D. & Co.) was injected for ten days and also three injections of 'Leucotropin' were given intravenously, without the slightest influence on the fever or the joint pains.

By 8th September, 1937, the patient was definitely worse. The elbow and wrist joints were greatly swollen and tender and did not allow of the slightest movement. Many types of embrocation were tried locally for the joint troubles and fomentations of turpentine, saturated sodium bicarbonate and magnesium sulphate were also exhibited, without any benefit or the slightest relief. Temperature now began to rise to 104° and 105°F., repeated rigors supervened followed by drenching perspiration, necessitating frequent changes of clothing.

I then began to suspect a septic infection and I sent several blood films and a sample of urine collected aseptically to the pathologist of the Sassoon Hospitals, Poona. Dr. Noronha, whilst reporting the absence of malarial parasites, stated that there was marked leucocytosis with a polymorphonuclear count of 80 per cent. The urine was reported to contain *Staphylococcus albus*, which it was suggested might possibly be a contamination. On receipt of this report I tried Prontosil, giving four injections between 11th and 16th September without any effect. Prostatic massage was done and the fluid thus obtained was also examined by Dr. Noronha and was reported negative to gonococcal infection.

As the patient was not improving nor responding to any line of treatment, I injected 0.05 c.c.m. of 'Staphylococcus Toxoid' (P. D. & Co.) on 20th September. This injection was given in view of the urine report and the clinical symptoms, namely fever, rigors and sweats, which made me suspect that the organism isolated from the urine might not be a contamination.

I decided on a hæmo-culture which was also done by Dr. Noronha who reported an abundant growth of *Staphylococcus albus* from the blood culture. I therefore persisted with the injections of 'Staphylococcus Toxoid' already commenced; the first injection of this toxoid gave a definite reaction as evidenced by a high rise of temperature. After the second injection on the 24th there was a noticeable improvement in the temperature, which touched normal and showed an evening rise to 100°F. only, and was also accompanied by an improvement in the joint trouble. A series of ten injections of 'Staphylococcus Toxoid' were given till 6th November, in addition to treatment to raise the general body tone and to combat the anaemia present.

At the end of this period, although the temperature showed a slight evening swing upwards, all the joints had cleared completely except the right wrist and the left elbow for which he received short-wave diathermy treatment.

The only link that was omitted in the establishment of the causative factor was the

examination of the fluid in the joints. I did not like the risk of a joint puncture for obvious reasons. It seems, however, that this does not affect the conclusion that I have arrived at, that the trouble was really due to the staphylococcus.

My view is that the primary source of the infection was acne, from which he was suffering. The previous course of the auto-vaccine that the patient received in England was probably responsible for the low virulence that the organism exhibited. One would have really expected a suppurative metastasis in the joint, in a staphylococcal septicaemia. Another point worthy of note is that the joints alone were involved and there were no other metastases elsewhere.

A PEDICLED AND PENDULOUS LIPOMA OF THE PERINÆUM*

By A. R. D'ABREU, F.Z.S., L.M.S.S.A. (Lond.)

Civil Surgeon, Gujrat, Punjab

A MAN, aged 40 years, an inmate of the Hissar District Jail, had a pendulous tumour arising from the perinæum behind the scrotum, which had been there for two years. The skin was freely movable over the surface and the consistence was that of a fatty tumour though

somewhat hard. As the tumour had begun to increase in size and weight to the inconvenience of its possessor, he consented to have it removed. The specimen was sent for examination to the bacteriologist to the Punjab Government, Lahore, who reported it to consist of adipose tissue with fibrous septa.

A CASE OF CHOPART'S AMPUTATION AFTER 15 YEARS

By M. G. KINI, M.C., M.B., M.Ch. (Orth.), F.R.C.S.E.
Surgeon, King George Hospital, Vizagapatam (S. India)

and
P. KESAVASWAMY
Radiologist

CHOPART'S amputation is not advocated in modern textbooks of surgery. It gives a very

* Abridged by the Editor.

good end-bearing stump if properly done and the following case illustrates this point :—

A female, aged 25 years, destitute, was admitted in 1935 for a swelling on the forehead. In her childhood at the age of 10 years, she sustained a railway accident as a result of which her right foot was crushed and was amputated.

On admission she was found to have venereal warts of the vulva, the Wassermann reaction was strongly positive and the swelling of the forehead was hard and bony, but just above the glabella it was soft and slightly fluctuating.

Fig. 1.—The clinical picture of the Chopart's stump.

Fig. 2.—The x-ray picture of the ankle joint and the Chopart's stump.

There was no pulsation or increase of size on coughing and the cranial nerves were normal.

The right foot is a perfect end-bearing stump. She had been walking without the aid of any appliance. Ankle movements were very good. Right calf muscle when compared with the normal side was not so well developed but all the muscles governing the ankle joint were functioning well. She was treated for her specific condition with great reduction in the size of the swelling on the forehead and disappearance of warts but the chief interest lay in the fact that this Chopart's stump had functioned well without any extraneous appliance.

MAY

LEPTOSPIROSIS

A SEVERE type of jaundice that appeared in epidemic form was described by Adolf Weil of Weisbaden in 1886, and from this time for some years there was a tendency to refer to all cases of severe jaundice that appeared in epidemic form as Weil's disease. In 1915 some Japanese investigators associated a slender coiled organism with a severe febrile attack, usually accompanied by jaundice, that occurred in both epidemic and sporadic form in Japan; this organism they recovered from the blood and urine of patients during life, and from the liver and kidneys post mortem.

In 1916 Uhlenhuth and other German workers found a similar organism associated with a form of infectious jaundice that occurred amongst the troops in the great war—especially amongst those in, or recently returned from, the trenches—and which had a comparatively high mortality (13 per cent). These organisms, now recognized as identical, are usually known by the name *Leptospira icterohæmorrhagica*, but the original German name *Spirochæta icterogenes* is still current.

Other clinical types of disease, which differ from the classical Weil's disease mainly in their severity, have been traced to infection with a leptospira that is morphologically indistinguishable, but serologically distinct, from the organism found in the classical disease; the word leptospirosis (λεπτος = slender; σπείρα = coil) has been applied to this disease group of which at least three types in human beings and others in animals are known, and probably many more are yet to be described.

It has been shown that all epidemics of jaundice are not due to a leptospira and the question has been raised whether the disease originally described by Weil was a true leptospirosis. This purely academic discussion, which, like the Shakespeare-Bacon controversy, can never be finally settled, is quite unimportant; the word leptospirosis can be used as the generic name of the group of diseases and Weil's name can still be honoured by its association with the particular clinical syndrome that approximates closely to his original description.

Leptospirosis has a very wide geographical distribution. The largest number of cases have been reported from Japan but perhaps this is only because physicians and research workers in that country have studied the disease more thoroughly. Considerable attention has been attracted to the disease in England recently and the cases described there now run into many

hundreds. Another European country where it is particularly prevalent is Holland. In the east, outside Japan, it has been known for some years in North Queensland, Java, Sumatra, Malaya, the Andaman Islands and Burma, and it seemed only to be a matter of time before it would be recognized in India. A number of clinically-suggestive cases were reported but it was only last year that for the first time the leptospira was recovered from a human case; this was a severe case of jaundice admitted to the hospital of the Calcutta School of Tropical Medicine (reported in our October number) and since this date Dr. B. M. Das Gupta has made a definite laboratory diagnosis of leptospirosis in four other patients. All these cases appear to have been sporadic, and there does not seem to have been any common factor in the nature of their occupations, types of residence, or even habits.

It is interesting that although for some years workers in India have been looking for cases of Weil's disease and although many of us are quite familiar with both the clinical picture and the technique for demonstrating the parasite, when eventually one case was identified, four more should be found immediately; the incident demonstrates the stimulating value of success. There is no suggestion that the disease has been imported recently or that any special circumstance has led to an increase in incidence. As long ago as 1932, Knowles and Das Gupta demonstrated the infection in Calcutta rats, though the infection rate (1 per cent) in these rodents was not as high as in other places (e.g., 40 per cent in Japan, 7 to 40 per cent in Holland, and 30 to 36 per cent in England); it would be interesting to see if recently there has been any increase in the infection rate amongst rats in Calcutta.

The most important improvement in the laboratory technique for the diagnosis of leptospirosis has been in the agglutination reaction and it is probably this that has led to the great advance in our knowledge of the epidemiology of the disease in recent years. Whenever a few cases have been discovered amongst a community or group of workers, it can nearly always be shown serologically that many others besides those showing symptoms have been infected; of these, some on being questioned will remember having had some fever with or without jaundice that may well have been a mild attack of the disease, whereas others will deny having had any illness. Thus, serological methods of recognizing the mild and sub-clinical infections have given us a much better idea of the incidence of leptospirosis amongst different communities and have demonstrated very clearly that it is an occupational disease.

Further, it has been shown that there are a large number of different serological strains and that to some extent the various strains have their own specific geographical distribution; that

is to say, there are eastern strains that are seldom encountered in Europe and *vice versa*, but curiously enough the first strain encountered in India was a European strain. Up to the present it has been shown that the organisms isolated from the Calcutta cases belong to at least two different strains.

The only epidemiological observation in the medical textbooks of a quarter of a century ago was that Weil's disease was common amongst young butchers. In western countries, slaughter-house workers still seem particularly liable to be attacked; the disease has appeared in epidemic form amongst miners, and is very prevalent amongst sewer workers and canal workers; it has occurred also amongst women engaged in cleaning fish and amongst others who prepare tripe. The sporadic cases have been mainly amongst people who have bathed in canals, or who have fallen or jumped into canals or docks and have swallowed or taken into their lungs large quantities of water. In Japan it has been reported mostly amongst miners, but in the Andamans it was found mainly amongst field workers, and in North Queensland amongst sugar-cane cutters.

In the epidemiology of the disease there appears to be one common factor, the rat, and in 95 per cent at least of the epidemic or even of the sporadic cases it is impossible to exclude the rat as a possible source of the infection. It would of course be hard to exclude this ubiquitous rodent as a possible source of infection in any disease, but the rat is so prominent a feature in all the surroundings in which the disease is acquired—in the trenches, in coal mines, in canals, in sewers, in slaughterhouses, and in the fields amongst certain crops—that it is impossible to ignore it, even without the further evidence that the leptospira can usually be isolated from the kidneys of a certain percentage of the wild rats caught in any locality where the disease occurs; it is almost certain therefore that this rodent is the most important reservoir of infection, even if it is not the only one: there is evidence that the dog, which is susceptible to infection by a species of leptospira, *Leptospira canicola*, has been the source of infection in a few cases.

Of the epidemiology of the disease in India we know nothing; as we have said above, there appears to be no common epidemiological factor in the history of the cases so far diagnosed, and though the rat as a source of infection could not be excluded there was certainly no particular reason to suspect that the infection originated directly or indirectly from rats.

In the rat the commonest site of infection is the kidney and the leptospira is present in large numbers in the urine. The mode of its entry into man is not certain; skin abrasions are considered to be the most likely route in the majority of cases, but in the cases of accidental immersion the micro-organism probably enters

via the respiratory tract, and in one water-borne epidemic the gastro-intestinal tract could not be ruled out. The disease has been contracted in the laboratory, where the entry may have been through the conjunctiva from a finger contaminated with guinea-pig's urine.

The incubation period is from 4 to 12 days and the onset is usually sudden, with fever mounting rapidly to reach 102°F. or 103°F. on the fourth day, continuing as a high remittent fever for a few days and then falling by lysis, the whole attack lasting about 10 days. The pulse is rapid at first but often slows down when the jaundice appears. Other symptoms are headache, stiffness of the neck, photophobia, redness of the eyes, pains in the muscles and joints, vomiting and severe prostration. Jaundice appears on the fourth day or later, but it is by no means a constant symptom, actually occurring in less than half the clinical cases. The tongue is thickly coated and there is usually obstinate constipation, though onset with diarrhoea is reported; there is a heavy cloud of albumin in the urine. Epistaxis and bleeding from the gums are common and hæmorrhages from other mucous surfaces may occur.

There is a polymorphonuclear leucocytosis and a progressive anaemia: the van den Bergh is haphasic and may reach 60 units of bilirubin. Rashes are not constant; a petechial rash may appear from the third to the fifth day, and a morbilliform rash from the fifth to the twelfth day: in very severe cases the rash is hæmorrhagic. The liver is usually palpable and the spleen occasionally; the former is nearly always tender.

The attacks vary very considerably in intensity and from serological evidence it is clear that the infection may be sub-clinical. The attacks in which there is no jaundice are never fatal, but epidemics in which the death rate was as high as 50 per cent have been reported. In its severest form the disease is difficult to distinguish from yellow fever, as was demonstrated in the classical instance when Noguchi discovered the leptospira in patients who had been shown to him as cases of yellow fever, and for a brief space of time, until the mistake was discovered, *Leptospira icteroides* was proclaimed as the causative organism of yellow fever.

The leptospira can be recovered from the blood during the first few days only, according to earlier reports, but recent evidence suggests that they are present up to the ninth day at least. Direct visualization with dark-ground illumination has been described, but is very difficult, and culture in Fletcher's medium or inoculation into young guinea-pigs is far more certain: 2 to 3 c.c. of blood is inoculated into the peritoneum of two or three animals, as occasionally they prove refractory to infection.

From the tenth day onwards, especially between the fifteenth and twenty-fifth days, the leptospira may appear intermittently in the urine, but they are only recoverable in about

one-third of the cases. Direct examination is again unsatisfactory as the organism may be morphologically atypical: cultural methods are difficult on account of the probability of contamination and guinea-pig inoculation is the most certain method: a few cubic centimetres of a centrifugalized deposit of urine taken aseptically are inoculated intra-peritoneally, and the guinea-pig usually dies with a fulminating infection by the tenth day, but from the fifth or sixth day the leptospira can be found in the peritoneal fluid, later in the blood and in the urine, after death the liver is the site where they can be best demonstrated.

Of the serological method, agglutination with live or formalized cultures is the most satisfactory. The titre is only 1 in 20 at the end of the first week, but rises rapidly and may be 1 in 1,000 at the end of the second and finally as high as 1 in 50,000. A high titre persists even for years in some cases. In the urine agglutinins of a titre up to 1 in 250 are sometimes present. Whenever possible a number of different strains should be used in the agglutina-

tion test and these should include examples of both 'eastern' and 'western' strains of *Lepto. icterohæmorrhagiae* and also *Lepto. canicola*.

Our original intention in introducing this subject was to draw attention to the recent confirmation of the existence that had long been suspected of leptospirosis in this country, and we have added a few notes on the clinical picture and the diagnosis for those of our readers who were not familiar with these details. This finding of not simply one sporadic case, or even of a localized outbreak, but of five separate cases from different parts of Calcutta suggests a widespread existence in India. Many will not have the laboratory facilities to confirm the diagnosis; to these the workers at the Calcutta School of Tropical Medicine will be pleased to give all possible assistance. If they are not too ill, and it is otherwise possible, the patients themselves should be sent, otherwise 5 to 7 cubic centimetres of blood should be collected, after the first week of illness, in a sterile ampoule and sent for serological tests to the protozoology department of the School.

Special Article

DIET AND THE INCIDENCE OF DISEASE IN INDIA*

By S. C. SEAL, M.B.

(Bacteriologist, All-India Institute of Hygiene and Public Health, Calcutta)

Deficiency diseases

MODERN workers engaged in the study of the relations of faulty food to disease are emphatic in their view that food is of paramount importance in the causation of disease. In India we encounter deficiency diseases of almost every kind, viz, xerophthalmia, night-blindness, phrynoderma, beri-beri, nutritional œdema, lathyrism, anæmia, scurvy, rickets, osteomalacia, pellagra, vesical calculus, goitre, angular stomatitis and certain skin diseases. In the northern parts of India, including the rural areas around Delhi, diseases associated with calcium and vitamin-D deficiency, e.g., rickets and osteomalacia, are met with, but these are comparatively less common in other parts of India. Urinary calculus occurs, for the most part, in the north of India and is relatively rare in the south, and its distribution seems to be related to the distribution of cereal crops, particularly wheat. According to McCarrison (1932), apart from infection and foreign bodies in the urinary tract, deficiency of vitamin A and deficiency of phosphates relative to the amount of lime in the diet are the most important contributory

factors in its production. Dental caries is widespread amongst Indians whose diets are composed mainly of cereals and are deficient in fat-soluble vitamins and vitamin C; it is more common in the northern area. Deficiency of calcium and phosphorus is also widespread. Even the Northern India diet, which according to McCarrison is the best in India, has been recently found by Mullick and Irving (1937) to be inferior to the standard diet of the Rowett Institute, Aberdeen, in respect to its calcium and phosphorus content. Rice which forms the staple diet of the majority of the population in India is poor in calcium and so are the drinking water and the vegetables. Thus, diseases associated with calcium deficiency are very common in India, and particularly in Bengal.

One of the causes of hypochromic microcytic anæmia common in infants and adult women during the child-bearing period is a diet poor in iron-containing foods. The normal hæmatological standard in the Bengali women is below the normal for European women.

Lathyrism and night-blindness are common in Bihar, in the Central Provinces and in the United Provinces, whereas nutritional œdema, xerophthalmia, beri-beri, pellagra, angular stomatitis, phrynoderma and certain other skin diseases are more commonly met with in Southern India and Ceylon. Goitre is prevalent in certain zones of Northern India below the great Himalayan range, where the iodine content of the soil and food materials is low, although the latter may not be the only factor concerned in its causation.

* Read at the meeting of the Public Health Society, Calcutta, held on the 21st December, 1937.

Diseases associated with suboptimal conditions of nutrition

McCarrison, who has a vast experience of these conditions in India, thinks that, besides the above-mentioned clearly-defined deficiency diseases, there are many maladies which are not usually regarded as of malnutritional origin, but according to the experience both in the laboratory and in the field these should be considered either wholly or in part of this nature, *viz*, gastro-intestinal diseases of various kinds including non-specific colitis and peptic ulcers, certain respiratory diseases often found in association with xerophthalmia, urinary calculus, some ulcers and cardiac disorders, pyorrhœa, and a number of others. These are perhaps due more to the faulty, unbalanced, and unvaried diets than to an actual gross deficiency. Nevertheless, they all ultimately lead to a state of malnutrition which is perhaps one of the important factors in causing the severe degree of maternal and child mortality and morbidity in India and is probably partly responsible for the state of lowered resistance to infection exhibited by so many of the Indian people. It may also, to a certain extent, account for the high mortality from malaria, kala-azar, cholera, dysentery, leprosy, tuberculosis, pregnancy anæmia, etc. In other words, as the soil is of greater importance than the seed, it is necessary to render it inhospitable to the growth of the seeds of these diseases by adequate nourishment of the body.

It is now generally recognized that much subnormal health and development, and even the incidence of disease are associated with a partial deficiency of one or more accessory food substances (M. R. C. Report, 1932). 'A race or community may be found in equilibrium with an environment which includes its food supply; and too often it is forgotten that while an equilibrium has been reached such a people may nevertheless be functioning at levels far below those possible to its innate capacities' (Hopkins, 1931). Fletcher (1932) also emphasized the presence in human beings of suboptimal conditions of nutrition which, without revealing any specific symptoms, yet weaken the resistance to infection or exposure and prevent the full efficiency and attainment which would have been possible with a food supply such as the newer knowledge of nutrition teaches. The experimental evidence of the above statements has been supplied by Sherman and others (MacLeod, 1935) in their investigation on animals.

Mann's experiments (1926) have shown that on a diet medically adjudged to be sufficient for healthy development boys were, in fact, not attaining to the physical and mental growth of which they had the potentiality and to which they did attain when given an extra daily ration of milk. Recently, Aykroyd and Krishnan (1937b) have obtained similar result, in their experiments with skimmed milk in some

South Indian schools. It seems that similar conditions also exist in most of the Indian races whose diets, though not as grossly deficient as the South Indian or Bengali diets, are no doubt below the optimal.

It is, however, rare that the food of human beings is totally devoid of any one vitamin, mineral, or proximate principle; it is more usual for the deficiency to be partial or of the borderline type and for more than one vitamin or principle to be at fault. It is more usual still, here in India, for partial deficiency of vitamins to be associated with deficiency of suitable protein and inorganic salts and with an excessive richness of food in carbohydrates. Consequently, the manifestations of disease resulting from the faulty food are due to the combined effect of the several degrees of *avitaminosis* on the one hand and of *ill-balancing* of the food on the other. This may be illustrated by the following average diet scales (*vide* table I) of several Indian races and nationalities of which a study of diet was either completely or partially undertaken, the difficulty in presenting a more accurate and reliable diet scale for each of the various nationalities being due to the fact that no extensive and thorough dietetic survey has been ever undertaken for any of them.

It will be evident from the above table that the staple article of diet of the Indian masses is a cereal grain of one kind or another, *viz*, rice, wheat, millet, maize and barley—and sometimes a mixture of two or more of these. Of these, again, rice forms the main source for the majority of the people in India. The defects and deficiencies associated with the use of milled rice in this country are now widely known and cannot be too often emphasized. There is, however, a good deal of difference in respect to the amount and quality of protein, the quality of cereal grains, the quality and quantity of fats, the minerals, vitamin contents and the balance of the food as a whole. In fact, there is a gradually diminishing value of food from the north to the east, south and west in India, the fall reaching the lowest limit amongst the rice-eaters of the east and south. There is also a gradual fall in the amount of animal protein, animal fats, and vitamins entering into these diets. The North Indian diets are mainly deficient in carotene, vitamins A and D and calcium content, whereas the Bengali diet is poor in total and animal proteins, total and animal fats, calcium and to a lesser extent phosphorus and iron. The same conclusion has been arrived at by Wilson, Almad and Mullick (1936) in their diet survey of some families and institutions in Calcutta. The South Indian diet, on the other hand, is grossly deficient practically from every point of view, *viz*, total calories, total and animal proteins, total and animal fats, carotene, vitamins A, B₂ and C, iron and calcium. Aykroyd and Krishnan (1937a) while making a diet survey in some South Indian villages noted that in poor families which showed

obvious lack of energy and initiative and a tendency to oedema the average caloric intake was only 1,664 per c.u. The situation in Madras has, however, been better depicted in the following table (table II) in which Aykroyd has recently compared the food supply per capita of Madras Presidency (1933) with that of Japan (1927) and of the United Kingdom (1934):—

other three groups respectively received the Central India, Bombay, and Bengal diets. At the end of the experiment the diets belonging to the above divisions ranged themselves in the following descending order of nutritive value: North India, Central India, Bombay, Bengal, and South India. It is needless to say that the same order or arrangement is found when different races are compared according to their

TABLE II

Comparison of the Madras Presidency diet with those of Japan and Great Britain

Nationalities	PROTEINS			FATS			Carbo- hydrate	Total calories
	Vegetable	Animal	Total	Vegetable	Animal	Total		
United Kingdom (1934)	41	46 (52.8 per cent)	87	15	109 (87.9 per cent)	124	425	3,246
Japan (1927)	72.6	15.9 (10 per cent)	88.6	14.2	3.5 (20 per cent)	17.7	537.6	2,732
Madras Presidency (1933).	40	2.6 (6.1 per cent)	42.6	36.5	1.3 (3.4 per cent)	37.8	398.5	2,068

Considering 2,500 calories per c.u. per adult man as the requirement in South India, the above figures fall short by at least 18 per cent; protein intake is low and that of both animal protein and animal fat is almost negligible. Besides, there are other defects already noted. On the whole, most Indian diets, as shown in the table, are *ill-balanced* when compared to the accepted standard and suffer mainly from deficiency of protein and to a certain extent fat. Carbohydrates on the other hand are rather in excess, and mainly account for the high total calories in some of the diets shown in the table. But the relative proportion of deficiency of other principles, *e.g.*, minerals, vitamins, etc., vary with different races, nationalities and provinces and the actual deficiency diseases from which they usually suffer are the ones enumerated at the outset.

Nutritive values of various Indian diets

The nutritive values of diets in common use in the five main racial divisions of India have been determined by feeding experiments on rats by McCarrison. All the animals were housed under identical conditions, and one group received a diet similar to that used by the Sikhs of Northern India, amongst whom some of the finest physical specimens of mankind are to be found. These animals grew at a normal rate and developed into perfect adults which kept remarkably free from disease. In other groups of rats fed on diets similar to those used by the less well-nourished people of the southern parts of India the growth curves were not satisfactory and there was a high incidence of disease cutting short their span of life. Among the diseases noted were infections of the respiratory organs, duodenal ulcers, etc., very similar to those found in human beings. The

physical developments, and that this difference in the nutritive values of these diets is perhaps reflected in the diseases from which the people of the north, east, and south of India usually suffer.

Relative values of diets compared to the distribution of diseases

McCarrison (1936) also compared the relative values of the above diets with the frequency of distribution of certain tropical diseases, *viz.*, pulmonary tuberculosis, leprosy, beri-beri, gastric and duodenal ulcers, diarrhoea, and dysentery, per 1,000 of the sick persons in these divisions. The result is shown in table III.

It will be evident from this table that the distribution of certain diseases is in inverse ratio proportional to the nutritive values of their diet irrespective of climate, race, environments, etc. That a close relationship exists between diet and the incidence of tuberculosis has now been long established, and there can be little doubt that want of proper nourishment of the body is the underlying cause of the appalling incidence of tuberculosis in this country.

Leprosy seems to have a similar tendency. This point was clearly defined a few days ago by Dr. Lowe (1937), the officer in charge of the leprosy inquiry at the Calcutta School of Tropical Medicine, in his discussion on the epidemiology of this disease. He agrees that leprosy does appear to be common among those people whose diet is ill-balanced and that in India the disease is much more common in parts where rice forms a staple part of the diet and when protein, fat and vitamins are little taken. He finds it common among the rice-eating

TABLE III

Showing the frequency distribution of certain diseases per 1,000 of the sick persons compared with the nutritive values of diets in the five main racial divisions in India (McCarrison)

Racial divisions	Relative values of diets expressed as average weight in grm. of the experimental rats	DISTRIBUTION OF DISEASES PER 1,000 OF THE SICK PERSONS				
		Pulmonary tuberculosis	Leprosy	Beri-beri	Gastric and duodenal ulcers	Diarrhoea and dysentery
North India ..	233	1.60	0.30	0.02	0.05	13.50
Central India ..	220	1.01	0.84	0.02	0.18	13.75
Bombay ..	198	2.01	0.70	0.02	0.06	15.00
Bengal ..	180	2.12	0.96	0.50	0.30	19.80
South India ..	155	2.61	2.95	1.03	2.60	19.20

people of Bengal, Bihar, Orissa and Madras and less common among people whose staple diet consists of wheat, jawar, or other grains richer in protein and among those who take milk and milk products. At the same time he has also pointed out that these differences in the incidence of leprosy in different parts of India may also be explained on the grounds of racial, climatic, and other differences, but he has no doubt that a good diet is an important thing in the prevention of leprosy and a good adjunct in its treatment. Similar findings have been made with regard to diet and leprosy in China and Africa. For instance, Dr. Mayer of Nigeria also concludes that poor food conditions, overcrowding of houses, prolonged period of drought and frequent famines cause increased susceptibility to the disease on account of the resultant starvation and dirtiness of clothing. These conditions, however, fit in well with those of Bengal district, Bankura and some places in Madras where leprosy is highly endemic.

In regard to malaria which occupies one of the foremost places—if indeed not the foremost—among the infective diseases in India, the Health Organization of the League of Nations

Proximate principles in relation to diseases

A. Proteins

According to western standards the minimum amount of protein that is required in a balanced diet is 100 grammes per m.v. per day, of which at least 50 per cent should be 'first class' protein, i.e., of animal origin. But as in the tropics for the oxidation of proteins, when used as a source of energy, an enormous amount of energy is necessary of which a great deal is given off in the form of heat, the percentage of proteins in the food of the inhabitants should not be too large. In view of this, the standard of 1 gramme of protein per kilogramme body weight per day is perhaps more suitable for this country than the western standard. But in most of the Indian diets not only does the quantity of protein fall much below this modified standard but very little protein of animal origin is included. The high figures of total protein in some of the diets shown in table I are mainly due to the vegetable proteins contained in the cereals taken in great excess. The following table (table IV) will illustrate the percentage distribution of the calories in different Bengali diets :—

TABLE IV

Showing the percentage distribution of calories in the Bengali diets

	BENGAL				Great Britain working classes
	Cultivators	Middle class A	Middle class B	Well-to-do	
Protein ..	8	9	12	12	12
Fat ..	10	20	35	47	25
Carbohydrate ..	81	71	52	41	62

has emphasized again and again in their reports that economic improvement is an essential preliminary. Colonel Gill, in considering epidemic malaria in North India, often preceded by a famine, says, 'The most important anti-malaria measures may not be antilarval operations, or even the systematic exhibition of quinine, valuable adjuncts though they may be, but the institution of measures to ensure that the labour force is properly housed and more especially properly fed'.

The average protein intake of the cultivators and the middle-class people who constitute the mass population in Bengal is in reality lower than even the average Indian figures. The amount of protein increases only slightly with the increasing income. The effect of this low protein diet particularly on the Bengalis has been studied by McCay (1910), Greig (1912) and others.

After discounting all other factors (climate, exercise, etc.) it has been quite clearly shown

that when protein allowance is materially reduced the people as a whole are less robust, mentally inferior, less enterprising, physically unfit for hard work, comparatively timid and meek by nature, and are subjected to various endemic and epidemic diseases. Orr and Gilks (1931) have supplied more convincing evidence of the above statement from the result of their investigation made on two African tribes in the Kenya colony, living under the same environment but on entirely different diets. One of the tribes, the Masai, live mainly on milk, raw blood and meat. They are a war-like race and are remarkably free from diseases, such as tropical ulcers, pneumonia, tuberculosis, etc. The other tribe, the Kikuyu, lives mainly on cereals. Their individuals are poorly developed, tropical ulcers are common and the mortality from pulmonary conditions is high. Moreover, chemical examination of blood of several individuals of each tribe has shown that the percentage of calcium is within normal range in the Masai whereas it is frequently below normal in the Kikuyu.

Proteins in relation to body defence forces and enzymes

A decided reduction of proteins weakens the defence of the organism against infection and this is probably due to the fact that the fluids of the body normally contain a great variety of the so-called antibodies which are highly complex substances and are protein in nature. Also, the digestive enzymes and other body ferments and the internal secretion of some ductless glands upon which depends the whole mechanism of food and body metabolism, and necessarily health, have been proved to be protein in nature. There should, therefore, be always a surplus of protein-building materials not only to meet the bare necessities of protein constructive processes that go on under normal conditions but also to provide for the steady and adequate supply of antibodies, enzymes, hormones and other body fluids mentioned above.

In the Bengalis, McCay (1908) has actually found deficiency in the percentage of floating proteins of the plasma, the low hæmoglobin value of red cells and lower blood pressure in the systemic arteries, all of which may be accounted for by the under-feeding. Recently Napier and Das Gupta (1935) have come to the same conclusion. That this lowering of the plasma protein plays an important part in the production of œdema has been shown by a large number of workers. The Bengalis are, therefore, predisposed to suffer from the œdema type of diseases owing to this unstable equilibrium caused by the low intake of protein resulting in low plasma protein, so that whenever the metabolic equilibrium is disturbed by either extrinsic or intrinsic factors, or both, the balance is upset and œdema caused as in epidemic dropsy, beri-beri, pregnancy, in the late stages of kala-azar, malaria, etc. Some of the other

Indian races whose diets more or less resemble that of the Bengalis are similarly predisposed.

B. Fats

Most Indian diets suffer in respect to the quantity of fat. No doubt in the tropics the standard laid down by the League of Nations for European countries, viz, 100 grammes with 50 per cent animal fat, will be excessive and possibly harmful, but the quantity actually consumed in this country does not reach half that standard. Again, the little fat that is used is usually of vegetable origin and hardly any animal fat, which contains vitamins A and D and some essential fatty acids, is included in the diet. In certain provinces, e.g., the Punjab, there are places where people rarely use fat in the form of pure fat or fatty oil, as commonly used in other parts of India. While people in such places suffer from clearly-defined deficiency diseases due to shortage of vitamins A and D, a far greater number of people in India accumulate no reserve of fat and develop a poor resistance against diseases of infective origin. Similarly, an inadequate milk supply both in quality and quantity is one of the most important factors in the causation of child morbidity and mortality in the provinces of Bengal and Madras. The consumption of fat is, however, dependent on the economic and social status of the people, there being a distinct tendency to spend more on fatty foods as the income increases (*vide* table IV).

C. Carbohydrates

The majority of the Indian diets are characterized by a great excess of carbohydrates which contribute about 70 to 80 per cent of the total calories consumed, in contrast with those of other countries, particularly of the west, which range between 50 to 60 per cent only. It has been found that when a diet contains all the essential ingredients, viz, proteins, fats, carbohydrates, minerals and vitamins in proper proportion and amount, the carbohydrate part is completely digested, but when the latter is in excess, both digestion and absorption are interfered with and other essential ingredients, such as proteins, vitamins and minerals, are also prevented from being properly and completely absorbed; this results in indigestion, sluggish liver, gastro-intestinal catarrh and chronic ill-health, loss of weight and greatly increased susceptibility to various infective diseases. The effects are much more pronounced in races whose main source of carbohydrate is rice. This cereal has many deficiencies, chief among them being those of calcium, phosphorus, and vitamin-B complex. Besides, its water content is high; it needs a large quantity of common salt for its consumption and has to be taken in large bulk to meet all requirements. The effects of rice on animal organisms, either alone or in combination with other food materials in common use by rice-eaters, were

studied in pigeons and monkeys by McCarrison (1932). Associated with the symptoms of ill-health and various diseases from which the animals suffered, conspicuous changes were noted in the gastro-intestinal tract, circulatory system, the endocrine organs and the nervous system, many of which have since been traced to particular deficiencies in the diet.

In conformity with the above observations parallel conditions such as poor stamina and muscular development, low powers of endurance and resistance to infection, etc., are found among the rice-eating races, particularly Bengalis, Madrassis and Oriyas. A parallel is also presented in the frequent occurrence among them of respiratory diseases, gastro-intestinal diseases (diarrhoeas, dysenteries, cholera, colitis, etc.), malnutritional oedema, various anæmias, skin diseases, beri-beri, and perhaps also epidemic dropsy. In this connection, it will be found in reference to table II that the diseases associated with gastro-intestinal catarrh, e.g., diarrhoeas and dysenteries, are, as expected, very common in all the five racial divisions in India and that there is a gradual and distinct increase in the proportion from the north (the Punjab) to the east (Bengal) and south (Madras), the two most important rice-eating countries.

The majority of the Bengalis recently studied by Pal and Ghose (1937) have been found to be suffering from some kind of gastro-intestinal trouble and their stools were highly acid in reaction, containing a fair amount of undigested starch. This acid stool and the other signs of fermentation in the middle-class people of Bengal are due to the consumption of more carbohydrate in their diet than is necessary for them, so that their function of assimilating carbohydrates becomes defective after a prolonged overstrain, and this combined with the deficiency of meat, milk and fruits, etc., ultimately leads to flatulence, hyperacidity, dyspepsia, hypoacidity, diarrhoea, dysentery, etc. In the Madras Presidency the incidence of gastric and duodenal ulcers and of gastric carcinoma is of more frequent occurrence than in any other province in India. Their ill-balanced and faulty diet has been considered as the exciting factor in producing the above conditions.

D. Vitamins and minerals

There is no doubt that milder grades of deficiency of certain food essentials, particularly of vitamins and mineral elements, are much more widespread among the Indian people than the severer grades. And it is also true that the less obvious manifestations of 'deficiency disease' are of vastly greater practical importance than the more obvious but less common diseases, such as scurvy, beri-beri, rickets, osteomalacia, etc., to which the term 'deficiency disease' is usually restricted. That this widespread occurrence of mild deficiency is directly

or indirectly responsible for a very large proportion of ill-health to-day, in India, can be shown even from the reports of school inspection which has recently been only half-heartedly undertaken in several provinces of India. The results obtained in 1934 and 1935 from inspection of schools in several provinces are shown in table V below.

The figures shown in table V, though only approximate and incomplete, reveal some interesting facts. A very large section of the children in each of the provinces mentioned are ill-nourished and in this respect the rural areas suffer much more than the urban areas. There is also a wide distribution of the affections of the eyes, teeth, nose, and tonsil including defective vision, hearing and speech, most of which can however be ascribed to some current or past illness of the respective organs. Skin troubles are also fairly common in Bengal, Bihar and the United Provinces. A high figure shown under 'enlarged spleen' in the rural areas of Bengal is probably due to the greater prevalence of malaria in this province. The position of Bengal, in concordance with the nutritive value of her diet, is most deplorable in regard to the physical condition of her school children. This has been further corroborated by Chatterji (1938) who has examined 33,151 Bengali students for physical development, health and nutrition. According to the standard developed by him 44 per cent have been grouped under 'malnutrition'. The situation of Madras is perhaps worse than Bengal. Although no regular survey has been made, the preliminary investigation into the state of nutrition of the school children in South India recently carried out by Aykroyd and his co-workers (Aykroyd, 1937) shows that the children have a low average 'weight for height', poor physique, and commonly suffer from angular stomatitis, xerophthalmia, and phrynodema (toad skin), etc. It may therefore be supposed that apart from various other factors which may predispose to the development of the above conditions a close relationship exists between the latter and the nature of the diet.

(a) Vitamin-B complex

One of the chief faults of the Bengali and Madrassi diets, as already mentioned, is a low content of vitamin-B complex and a composition which increases the need of vitamin B. This deficiency perhaps plays an important part in, and partially accounts for, the great prevalence of gastro-intestinal disorders in these two provinces. Because of the high incidence of gastro-intestinal diseases in his experimental animals McCarrison (1920) was led to believe that a liberal supply of vitamin B₁ is very important in maintaining the health of the gastro-intestinal tract and that its want is a common cause of gastro-intestinal ailments. Among the most recent results obtained in this connection

are those published by Baker, Wright and Drummond (1937) who have found that the

gastro-intestinal troubles. The observations recorded by the Swedish investigators (1934)

chief effect of prolonged use of vitamin-B-deficient diet is the remarkably high incidence of

carried out on 17,400 healthy and sick persons provided additional evidence that faulty diet

(particularly 'L-diet'*) deficient of vitamin B is an important cause of gastro-intestinal diseases (e.g., achylia, gastric discomfort, colitis, constipation, diarrhoea, etc.) and anæmia. Pfaffenberg and Mielke (1937) have found benefit in such cases with vitamin-B therapy, particularly in those which were associated with diseases affecting the gastro-intestinal tract, e.g., pellagra, sprue, achlorhydria, etc.

Apart from the gastro-intestinal disorders, certain types of anæmia and a few other diseases in this country have been associated with the deficiency of vitamin B. Thus Napier (1936) found that a diet rich in vitamin-B complex effected a cure in certain anæmias in Bengal (recent work tends to show that vitamin B₁₂ is an anti-anæmic factor); while Wilson and Ghosh (1937) observe that the bisulphite-binding power is increased in the blood of cases of epidemic dropsy, anæmia, splenomegaly and diabetes, indicating that there is a deficiency of vitamin B, or of allied vitamin in the above diseases in Bengal. Basu (1938) finds that the addition of vitamin B₁₂ has a retarding effect in the experimental production of nodular leprosy in white mice and he has observed improvement in several leprosy cases with anæsthetic patches by treating them with vitamin-B concentrate from yeast.

One of the important factors predisposing to anæmia of pregnancy is undoubtedly a deficient diet particularly during the antenatal period. Wills (1931) showed that vitamin-B deficiency was the cause of a type of macrocytic anæmia in Bombay. Skin affections, impaired digestion, sluggish bowel action and impaired growth, from which many children in this country suffer during the lactating period, are due to a constant mild grade deficiency of vitamin-B complex in the milk.

(b) Vitamins A and D

Similarly, many of the diseases of Indian women and children are directly or indirectly attributable to the faulty or deficient diet. Rit (1937) is inclined to the view that deficiency of vitamin A plays the primary rôle in the causation of infantile diarrhoea in Bengal and he has treated with great success several cases with halibut-liver oil containing a high percentage of vitamins A and D. Mudaliar and Menon (1932) think that deficiency of vitamin A during the antenatal period greatly predisposes the mothers to puerperal sepsis and they have obtained uniformly good results by the administration of cod-liver oil as a prophylactic, both during and after labour, and also when used in certain prolonged fevers in the puerperium associated with signs of sepsis. Further and much closer investigations are, however, necessary to give the final opinion on this subject. Similar results have been obtained in

* 'L-diet'—An unvaried diet consisting of refined flour, milk, potatoes and little butter, with little or no meat, fresh fruits, or vegetables.

other countries as well. For instance, Spiegel (1937) treated 11 cases of chronic ulcerative colitis in which other forms of treatment became ineffective, by rectal instillation of cod-liver oil emulsion by means of Murphy drip or a partly clamped enema bag with very satisfactory results.

Evidence of sub-clinical shortage of vitamins A and D, e.g., affections of eyes, teeth, tonsils and skin, prevalence of adenoids and respiratory diseases, etc., will also be found in the school inspection reports given in table V. These are mainly due to the want of sufficient and good quality of milk and animal fat in their diets. Although this might be supplemented by the carotene content of the leafy vegetables and fruits, unfortunately these articles are also only sparingly taken. Moreover, the percentage absorption of carotene on a fat-free diet is about half that on a similar diet containing fat (Wilson, Das Gupta and Ahmad, 1937) and most of it is destroyed by the high heat during the process of cooking, to which these vegetables are invariably subjected before eating.

It has been shown by Roller and Wills that vitamin A is a vital necessity for the normal functioning of the gastro-intestinal tract and that a deficiency causes degeneration of mucous membranes. Recently Moir (1938) is inclined to associate the very high incidence of gastric carcinoma in Anglesey, North Wales (as reported by Empire Cancer Campaign, *B. M. J.*, 11th December, 1937, p. 1181), with that of vitamin-A deficiency which is well marked in that part of the country. While such relationship may be a mere coincidence it may be mentioned that a similar speculation can also be made for the distribution of cancer in India where the incidence of gastric carcinoma is highest in the Madras Presidency, the population of which greatly suffer from the deficiency of the above vitamin.

(c) Vitamin C

Spongy and unhealthy gums, carious teeth, aching in joints and ankles with occasional swelling, painful legs, etc., which are fairly common in this country, and some of which are usually mistaken for rheumatism, have often been proved to be due to insufficient vitamin C in the diet. Pyorrhœa alveolaris is frequently found in persons whose diets contain far too little fresh vegetable foods. Although it is difficult to conceive the condition of actual vitamin-C shortage in a country where plenty of green vegetables and fresh fruits may be obtained, there is undoubtedly a sub-clinical shortage of this vitamin particularly due to the fact that it is easily destroyed by heat and boiling to which all foods are subjected before eating. This condition is especially applicable to Bengal where, in addition to the defect caused by cooking, fruits and milk are very sparingly taken. Children in this province are usually irritable,

lacking in stamina and are more or less retarded in growth. And it has been shown that they can be restored to better growth, higher stamina and better general health and disposition by feeding an additional amount of vitamin C in the form of orange juice, tomato juice and other suitable anti-scorbutic foods.

Gastro-intestinal troubles, such as hyper-acidity, pain, indigestion and gastro-duodenal ulcers, are very common in this country. A large number of workers have definitely associated vitamin-C deficiency with the incidence of peptic ulcers and claim that a definite improvement has followed a liberal or excess supply of vitamin C in such cases. The references on this subject may be found in a very recent paper by Lazarus (1937), in which he has shown the presence of a state of sub-scurvy in patients with peptic ulcer, particularly in cases complicated by hæmatemesis and melæna. On the evidence of clinical observation the author has recommended a liberal supply (200 m.gm.) of ascorbic acid daily and emphasizes the importance of maintaining the general condition, health and nutrition in such cases.

These ulcers have a peculiar distribution in India being common amongst the rice-eaters of Bengal and South India, and are very prevalent in Travancore. It has been shown in the laboratory that the tapioca diet of the poorer class Travancorians will cause this condition in 27 per cent of the albino rats fed upon it, that of the poorer class Madrassi in 11 per cent, while the lacto-vegetarian diet of the Sikh affords the animals complete protection against it.

There are perhaps other diseases, in this country, in which a sub-clinical shortage of vitamin C may be found, e.g., anæmia, epidemic dropsy, etc. In short, mild grade of hypo-vitaminosis is supposed to be the cause of high incidence of so many tropical diseases in this country.

In this connection it will be interesting to note that a pernicious type of anæmia may be produced in albino rats by feeding them on a diet of oatmeal, linseed meal and patent flour (McCarrison, 1932). It is caused by *Bartonella muris*, the rat-loose-borne organism which is also known to produce a profound anæmia in splenectomized animals of this group. This finding, as McCarrison also pointed out, has a great significance in malaria, kala-azar and splenomegalies—diseases widely prevalent in this country and favoured in their course and development by famine conditions—as the protective resources of the spleen may be injured by faulty nutrition in a way comparable to that brought about by splenectomy in rats.

Overeating

Before concluding, a few words may be said about the incidence of diseases associated with overeating. There is, no doubt, a small group of men amongst all nationalities who indulge in

this practice and ultimately fall victims to dyspepsia, indigestion, diabetes, heart and kidney troubles, high blood pressure, etc. They are usually large-type men and may be called the 'plethoric' type. Their condition is much the same as observed in other countries and they generally have shorter lives than the average. Diabetes is fairly common, particularly in Bengal, and although overeating is one of the most exciting factors it is perhaps more due to high carbohydrate diet and lack of exercise than to actual overeating. Nevertheless, this question is not so acute in this country at the present moment as that of underfeeding and ill-feeding.

Conclusion

From what has been stated above it may fairly be concluded that a general dietetic deficiency is more or less prevalent all over the country and that apart from the clinically-defined deficiency diseases enumerated at the outset a sub-clinical state of deficiency is the primary cause of the general ill-health and lowering of resistance of the various races and nationalities represented in India and is indirectly responsible for the most severe ravages of this country by the various tropical diseases, such as malaria, kala-azar, tuberculosis, leprosy, cholera, gastro-intestinal disorders, anæmias, diarrhœas, dysenteries, etc.

The problem of nutrition in India can thus be resolved into a single question: 'What are the effects of diets composed mainly of cereals (carbohydrate) and deficient in proteins, fats, minerals and vitamins on the people using them and how to remedy the defects?' This problem may be approached in two ways: (i) by an epidemiological survey of diseases with special reference to dietary conditions, and (ii) by animal experimentation and food analysis. The latter has, to some extent, been followed in several laboratories in India and although studies in this line are yet grossly incomplete, the results already obtained sufficiently warrant the conclusion that widespread mild deficiency is present almost all over India. In regard to the former method, however, the work has never been undertaken so seriously in this country, but the possible relationship of tuberculosis, leprosy, epidemic dropsy, respiratory diseases and gastro-intestinal disorders, e.g., diarrhœa, dysentery, cholera, peptic ulcers, etc., to dietetic deficiency has been indicated. It may also be suggested that the incidence of other general diseases, such as, malaria, kala-azar, splenomegaly, etc., is, to a certain extent, dependent upon the nutritive factor as well. In view of this, along with the dietetic survey, one on epidemiology of the diseases should be simultaneously carried out and the rôle of intestinal flora in the incidence of diseases should also be investigated. It will be found that the solution of the problem of prevention of diseases in India is one of improvement of conditions of

living as of food supply of the people by improvement in the methods of agriculture, animal husbandry and industry and lastly by restraint on reproduction.

'The use of properly constituted diet is a sure means of attainment of physical efficiency and health' (McCarrison).

Medical News

SUMMARY OF TUBERCULOSIS NEWS FOR THE MONTH OF MARCH 1938

THE 24th annual conference of the National Association for the Prevention of Tuberculosis, London, will be held in the Great Hall, British Medical Association, Tavistock Square, London, W.C.1, on 30th June and 1st and 2nd July, 1938, and will be preceded by an annual meeting of the Care Committee on 29th June, 1938 (in the morning).

Major-General E. W. C. Bradfield, C.I.E., O.B.E., K.H.S., I.M.S., chairman, King George Thanksgiving (Anti-Tuberculosis) Fund, and Lieut.-Colonel C. M. Nicol, I.M.S., chairman, Punjab Provincial Anti-Tuberculosis sub-committee, have been nominated by the central fund committee of the King George Thanksgiving (Anti-Tuberculosis) Fund as official delegates for this conference.

Eleventh Conference of the International Union against Tuberculosis

In accordance with the recommendation of the executive committee, the council of the Union has decided to summon in Berlin in 1939 the next conference of the International Union against Tuberculosis. The exact dates will be decided later. The executive committee has suggested the following subjects for discussion on the agenda of the conference:—

Biological subject.—'The problem of the virulence of tubercle bacillus'.

Clinical subject.—(a) 'The value of systematic examinations for the diagnosis of pulmonary tuberculosis'.

(b) 'Intestinal tuberculosis'.

Social subject.—'The rehabilitation of the tuberculous. The best conditions of work'.

Her Excellency the Marchioness of Linlithgow's Appeal for the King-Emperor's Anti-Tuberculosis Fund

The position as regards collections as on 21st March was that Rs. 23,89,423 had actually been received and banked in New Delhi. Collections actually made in the Provinces and States, but which have not been remitted to New Delhi, total a further Rs. 11,67,750—making the total just over Rs. 35½ lacs.

Comparisons with the collections for the Silver Jubilee Fund in 1935, when a total of just over 128 was available, cannot be completely satisfactory. But, so far as can be gauged, collections for Her Excellency's appeal are in advance at present of those for 1935; and it is to be hoped that this progress will be maintained.

The cause must appeal to everyone.

HER EXCELLENCY'S ANTI-TUBERCULOSIS DRIVE

PLANS are now being actively prepared for an intensification of the campaign on behalf of the Marchioness of Linlithgow's appeal for the King-Emperor's Anti-Tuberculosis Fund.

Efforts are being made to focus public attention on the need to fight a disease which is playing such havoc with Indian lives, and to secure the widest possible support for the Fund, which has already met with a good response both in British India and the Indian States.

Proposals are being considered for the preparation of a film to be shown throughout the country, and for a series of broadcasts which will indicate the incidence of the disease in India and outline the new proposals to counteract it.

Great Britain's interest

Deep interest in the Fund is also being shown in Great Britain where a group of influential people have recommended it to the British public.

It is anticipated that provincial fund committees which have been formed will also be able to promulgate its aims and purposes in lectures. Leaflets, pamphlets, and posters are being prepared for all-India distribution, and special efforts will be made to reach the rural population by means of publicity carried out in the vernaculars. Suggestions have been made that exhibition booths should be established at important *melas* throughout the country, to supply visitors with literature regarding the disease and to bring the Fund to their notice.

The tuberculosis menace has world-wide incidence, and the Fund now established is intended to bring the most scientific ideas to help in minimizing its ravages in this country and to benefit from the research which has been carried out elsewhere.

The need for developing preventive and curative measures in the rural areas is everywhere emphasized, and the hope is expressed that the public response for funds will be immeasurably strengthened by an educative campaign showing the perils of the disease and indicating the means by which they may be combated.

More serious than cholera

The people of India are deeply concerned at the prevalence of tuberculosis in the country. There is no doubt that tuberculosis, usually in the pulmonary form, is the most insidious disease that India has to face; it is more serious than plague or cholera, because although those diseases come in severe epidemics their heavy mortality does not last long, while tuberculosis is always there exacting a heavy and constant toll.

This toll falls principally on the most valuable section of the population, on the young adults; on the young men, the breadwinners of the family or the students, and on the young women who are mothers and who keep the home together. It is impossible to state with complete accuracy how many die each year in India from tuberculosis, because the vital statistics throughout the country as a whole are not sufficiently complete.

'Many deaths from tuberculosis are undiagnosed and unreported'.

Some Indian cities

Even as it is the cities of Poona and Ahmedabad report that one out of every 12 deaths occurring in their limits is due to tuberculosis: Cawnpore reports that one in every 11 deaths is from tuberculosis and in Calcutta the number is regarded as being higher.

Here is a brief statement showing by comparison the number of deaths from pulmonary tuberculosis per 100,000 of population in certain cities of England in 1933 and of India in 1934: only a few cities including the worst in each country are given.

Ipswich	53
London	82
Birmingham	86
Manchester	104.
South Shields	138
Lucknow	223
Calcutta	230
Poona	324
Ahmedabad	389
Cawnpore	422

Cawnpore and Ahmedabad may be called the Manchesters of India, for their industries are similar to those of Lancashire: their mortality rates are a contrast. But the real figures for Indian cities are for the reasons above stated certainly higher than those here given: it has been estimated that in Lucknow probably about one in every seven persons dies from tuberculosis.

Increasing

Whatever the actual figures may be the number of tuberculosis deaths in India is very large; there is a general feeling that it is increasing.

History shows that when a rural agricultural people begin largely to change their mode of life, to move into the cities, and to take to indoor and factory industries, they tend to become heavily infected with tuberculosis. Primitive people are free from tuberculosis, but very susceptible to it; so long as they do not meet the germ of the disease they remain healthy.

Gurkhas' death rate

This fact is exhibited by the tuberculous death rate of Gurkhas who come from the more isolated areas of Nepal as compared with that of the other races of soldiers in the Indian Army: during 1935 the tuberculous mortality rate among Gurkhas was three and a half times that amongst sepoys from the rest of India.

It is again exhibited by the higher tuberculous death rate in the Bombay police force of the Pathan constables as compared with their Mahratta colleagues. During the process of adaptation to a city or industrial life primitive folk suffer heavily from tuberculosis, until at last when the nation becomes accustomed to urban life and when the people have acquired in time clean cities and good laws of health they suffer less because by this time they have largely acquired an immunity to the disease.

European experience

Examination of the city population of Europe shows that over 90 per cent of the adults have been infected with tuberculosis, but they do not suffer from it so much because having acquired some immunity they are able to resist the disease. That is the story of tuberculosis in England and Wales and Scotland.

When England began to change from an agricultural to an industrial country in the eighteenth century the death rate from tuberculosis was appalling. How high it was is not exactly known as registration was not perfect then, but it remained very high throughout the first half of the nineteenth century and then from 1865, by which time satisfactory statistics were obtained, the death rate began to fall steadily and has continued to fall until the present day.

A successful fight

The same story may be told of the history of tuberculosis in the United States of America, though here the improvement was later and it was not until the year 1900 that the decrease in tuberculous diseases began; but when it began the decrease was so rapid that the cities of that country are, so far as tuberculosis is concerned, among the best in the world. In 1930 the death rate from pulmonary tuberculosis in Chicago per 100,000 of population was only 56, while for Calcutta the reported figure was as much as 240.

The cities of Europe can tell a similar story of improvement achieved, and of further improvement still proceeding. In India the people are still highly susceptible to tuberculosis: they are in the intermediate stage above described and the death rate is very high, and perhaps still increasing.

What India has to face

That is the position India has to face.

'It is all important not only that her people should realize the position, but that they should act upon a definite plan, following a campaign against the disease that shall be centrally advised and locally carried out.

Haphazard effort and the uncontrolled charity of local philanthropists or of municipalities are likely to lead to the establishment of a few sanatoria and dispensaries here and there working without co-ordination either with health authorities or with one another.

India however has the experience of other countries to guide her and an epitome of their experience is well given in a recent Bulletin of the Health Organization of the League of Nations.

The organization declared that only limited results and at enormous expense could be expected from treatment only; and no country has yet been able to afford sufficient sanatoria for all its cases of tuberculosis. Following the League's advice the tendency is to turn towards 'preventive medicine and social hygiene whose essential weapon is the dispensary'; in co-ordination with the dispensary will work tuberculosis hospitals and settlements. On the social side chief attention must be to housing, to education and to nutrition, especially of children.

Both His Excellency the Viceroy and Lady Linlithgow are taking the keenest personal interest in the problems of nutrition and tuberculosis in India, and it is hoped that under the controlling ægis of the King-Emperor's Fund, the people of India will be aroused to co-ordinate effort and that the campaign against the disease will show increased activity and truer direction.

RED CROSS AND ST. JOHN AMBULANCE

H. E. THE VICEROY'S TRIBUTE

'His Excellency THE VICEROY had words of high praise for the work of the St. John Ambulance Society and the Indian Red Cross in his address at the joint annual general meeting of the two bodies, held in the Viceroy's House, New Delhi, on 24th March'.

H. E. The Viceroy said:

It is gratifying to hear again of the satisfactory progress during the year to which Sir Ernest Burdon has referred to in his report both as far as the St. John Ambulance Association and the Indian Red Cross Society are concerned.

To one whose daily bread is the study of politics and its conflict of interests, it is encouraging to turn to a sphere of activity where enthusiasm and unity of interest in humanitarian activity contrive to produce such satisfactory and beneficial results.

I am glad that your chairman referred to the All-India Ambulance competitions which took place at the Irwin Stadium, New Delhi, from 2nd to 4th February of this year. I would like to congratulate those who were responsible for the organization of those competitions. I was much interested in what I saw of them and I am convinced of the value that these competitions have, not only for those who are members of the association already, but for the general public as a whole who must realize from them the value of the work which the association does.

I agree, too, with the chairman as to the value of the organization of classes in 'Air-Raid Precautions'. In any work such as that with which your association is concerned, 'Be Prepared' is as sound a watchword as in any other. But I am sure I express the hope of all present here that the day will be far distant when the lessons learnt will have to be put into effect.

Indian Red Cross Society

The Indian Red Cross Society too deserves its full share of congratulation for its valuable activities in connection with affairs outside India as well as within India itself.

I am particularly gratified to hear of the increase in numbers of the Junior Red Cross and the valuable part that the school groups are playing in village improvement work. You know my interest in the problem of nutrition and the activities of the Red Cross Society in that respect have my fullest support.

I am convinced too of the value of the film and wireless in disseminating knowledge with regard to public health. I hope that the Headquarters Cinema Section which has been so successful hitherto will be

able to see its way to extending its activities and preparing more films. And here I would like to congratulate the Punjab Red Cross on receiving a gold medal at the All-India Industrial Exhibition in Lahore for its exhibits in connection with health and child welfare.

We have full occasion to-day to congratulate ourselves on the activities of the past year. But I must, too, record the grievous loss which the societies will incur by the termination of the services of Miss Norah Hill who for nine years has been the organizing secretary of these two great institutions.

I would like to refer to the Anti-Tuberculosis Appeal of which Sir Ernest Burdon made mention in his speech.

I think it is now generally recognized that, given persistence and enthusiasm, this appeal has within it the power to render service of outstanding value in the annals of health work in India. In such appeals, as you will all recognize, much depends on hard work and enthusiasm both in the early stages and in later times when there is the possibility that interest might die out.

THE INDEPENDENT MEDICAL PRACTITIONERS' ASSOCIATION, TINNEVELLY

THE first anniversary meeting of the above association was held on 12th March, 1938, under the presidency of Dr. R. Sundaram, M.B. After the reading of the annual report of the association by the secretary, Dr. D. V. Venkappa, the provincial secretary, the All-India Medical Licentiates' Association, Madras, read the memorandum submitted by that association on the G.O. on the honorary system of medical service, published by the Government of Madras a few months back and gave a short résumé of the salient defects in the system.

Then Dr. R. Sundaram delivered his address—'Our Profession: Some Thoughts'. He traced the progress and development in medicine and surgery during the past 50 years. He dealt with the advances made in anaesthesia, in tropical medicine, in bacteriology and biochemistry, endocrinology and hormone therapy, radiology and radium therapy, neurology and psychiatry, and in therapeutics. Regarding the future of the profession, he said more attention should be paid to the preventive side rather than to the curative, and spoke a few words regarding the correct code of conduct for medical men, and wound up his lecture by saying that medicine, though a noble profession, is a sorry trade and, if the making of money is the chief aim of man, this is not the profession for him. After the usual vote of thanks the meeting terminated.

THE DR. B. S. SHROFF MEMORIAL GOLD MEDAL OF THE BOMBAY MEDICAL UNION

THE following subject has been selected by the Bombay Medical Union for competitive thesis for the above prize for 1938:—

'Tuberculosis in general, paying special attention to its prevention and treatment'.

The award will be in the form of a gold medal called the Dr. B. S. Shroff Memorial Gold Medal of the Bombay Medical Union.

The competitor must be (i) a duly qualified member of the medical profession holding a degree or degrees and diplomas from Indian and other universities created by statute, or (ii) a duly qualified member of the medical profession holding the diploma of Membership of College of Physicians and Surgeons of Bombay. The thesis must be sent in six typed copies so as to reach the honorary secretaries, Bombay Medical Union, Blavatsky Lodge Building, French Bridge, Chowpatty, Bombay, on or before the 15th August, 1938.

The thesis should be designated by a motto instead of the writer's name and should be accompanied by a sealed cover containing the name of the writer and his post-office address.

The name of the prize, the year of competition, the subject of the thesis and the writer's motto should be superscribed on the cover.

No study or essay that has been published in the medical press or elsewhere will be considered eligible for the prize, and no contribution offered in one year will be accepted in any subsequent year unless it includes evidence of further work.

The accepted thesis shall be the property of the Bombay Medical Union.

All other theses shall be returned if not accepted, provided the return postage expenses are paid in advance by the writer.

In the award of the prize to the successful candidate, the decision of the committee shall be final.

Hon. Secretaries,
BOMBAY MEDICAL UNION.

Bombay, 15th February, 1938.

ANNOUNCEMENT OF THE FRANCIS AMORY SEPTENNIAL PRIZE OF THE AMERICAN ACADEMY OF ARTS AND SCIENCES UNDER THE WILL OF FRANCIS AMORY

In compliance with the requirements of a gift under the will of the late Francis Amory of Beverly, Massachusetts, the American Academy of Arts and Sciences announces the offer of a septennial prize for outstanding work with reference to the alleviation or cure of diseases affecting the human genital organs, to be known as the Francis Amory Septennial Prize. The gift provides a fund, the income of which may be awarded for conspicuously meritorious contributions to the field of knowledge 'during the said septennial period next preceding any award thereof, through experiment, study or otherwise . . . in the diseases of the human sexual generative organs in general'. The prize may be awarded to any individual or individuals for work of 'extraordinary or exceptional merit' in this field.

In case there is work of a quality to warrant it, the first award will be made in 1940. The total amount of the award will exceed ten thousand dollars, and may be given in one or more awards. It rests solely within the discretion of the academy whether an award shall be made at the end of any given seven-year period, and also whether on any occasion the prize shall be awarded to more than a single individual.

While there will be no formal nominations, and no formal essays or treatises will be required, the committee invites suggestions, which should be made to the Amory Fund Committee, care of the American Academy of Arts and Sciences, 28, Newbury Street, Boston, Massachusetts, U. S. A.

HUNTERIAN SOCIETY

GOLD MEDAL FOR PRACTITIONERS

ANY registered general practitioner resident within the British Empire is eligible to compete, and the medal, which is of gold, is awarded annually to the writer of the best essay on a subject selected by the Society.

Competitors, men or women, must be engaged in general practice, and essays should be sent in by 31st December.

The essay must be unpublished and original, and be based on the candidate's own observation, but it may contain excerpts from the literature on the subject, provided that reference be made to the articles from which they are taken.

A copy of the rules and any further information can be obtained on application to the Honorary Secretary, Mr. Arthur E. Porritt, 27, Harley Street, W.1.

The subject selected for the essay is:—

1938. 'The Management of Inoperable Malignant Disease in General Practice'.

1939. 'Treatment of Obesity in General Practice'.

The 1937 Hunterian Gold Medal for General Practitioners was won by Dr. J. Wilson Reid, of Anglesey, for his essay on:—

'The Prognosis and Care of Heart Disease in General Practice'.

ENQUIRY INTO MEASURES OF REHABILITATION OF PROSTITUTES*

THE provision of social, as well as medical, services in the treatment of venereal disease is a comparatively new feature of social work. The League of Nations Secretariat has just issued an account of the systems prevailing in different countries, acting upon a resolution of the 1937 Assembly that 'an early publication of this information will be of great service to countries contemplating the creation or extension of such services'.

Replies from over forty countries to a questionnaire show that the necessity for cheap medical treatment for venereal disease is now widely recognized. In some countries such treatment is compulsory by law for all sufferers and, as regulated prostitution declines, this group of countries, already the largest, recruits new members; in others, it is only compulsory for prostitutes; and in eight countries, including the United Kingdom, treatment is voluntary, but is encouraged by facilities organized or subsidized by the State, and by propaganda and instruction.

There is not the same wide recognition of the need for social help, and the number of countries where social service is combined with treatment at venereal disease clinics and hospitals is still comparatively small. In countries where social services exist they take different forms. An account is given of the systems in force in two of the countries which rely on individual social assistance—the United Kingdom and France. In the former country help is given through the hospital almoner, who acts as the link between the patients and the social and charitable institutions which might be useful to them; through hostels attached to the public hospitals in London where women recommended by the treatment centres are given free or cheap board and lodging and some general education and training in work and are helped to find employment when they leave, and through training in hospitals. In France the patients are helped by workers attached to hospitals as social assistants. Other countries, such as the Union of Soviet Socialist Republics, whose system is described, have set up special institutions for combined medical and social treatment.

Although it is as yet too early for any method to have proved itself unquestionably the best, the report suggests certain guiding-lines for future planning and should prove of value to social workers in all countries.

DISTINGUISHED SERVICES

THE name of Major-General N. H. Hamilton, C.B., C.I.E., C.B.E., D.S.O., F.R.C.S., I.M.S., K.H.P., Deputy Director of Medical Services, Northern Command, India, has been brought to notice by H. E. the Commander-in-Chief in India for distinguished services rendered in connection with operations in Waziristan, N. W. F. of India, 17th January to 15th September, 1937.

THE FACULTY OF TROPICAL MEDICINE AND HYGIENE, BENGAL.

The following students are declared to have passed the D.T.M. Examination, Session 1937-38.

Passed with distinction

1. Chanan Lal, L.S.M.F. (Punjab), Medical Officer, Civil Hospital, Rawalpindi.—Awarded the 'Chuni Lal Bose' Gold Medal, 1938.

*Series of League of Nations Publications, 1938. IV, 1, 66 pages. Price: 1/3; \$0.30.

Current Topics

Injection Treatment of Hernia

(Abstracted from the *Journal of the American Medical Association*, Vol. CIX, 30th October, 1937, p. 1456)

THE recent wave of enthusiasm over the injection method of hernia had its impetus in the success of sclerotherapy in various veins and hæmorrhoids. Some disappointment with the results of surgical procedures, particularly in cases of direct inguinal hernia, was an additional reason for the revival of a method long relinquished and tainted by quackery.

According to recent reports by Bratrud, Rice, Harris and White, and Fowler the rationale of the treatment depends on the property of mildly irritant solutions to produce a fibrosis when injected into normal tissues, and on the ability of the fibrosis thus produced to obliterate the inguinal canal by causing an intimate adherence of the muscular layers in this region by much the same mechanism as that obtained by suturing. Harris and White injected such irritants into the muscles of the thigh in a group of normal guinea-pigs. They found that these solutions provoked a polymorphonuclear leukocytic response of short duration, followed by a gradually increasing reaction from the mononuclear mesenchymal elements, which later differentiated into spindle cell fibroblasts, resulting in fibrosis. MacMillan and Cunningham, Fowler, Rice and others have obtained similar results. Rice has obtained microscopic proof of the occurrence of fibrosis in human beings in biopsies from patients who have been operated on for the cure of hernia after having submitted to one or two injections at varying intervals before the operation was performed.

The injection method, according to its modern advocates, is applicable only to hernia that can be completely reduced and kept reduced by means of a truss.

Its use is contra-indicated in irreducible hernias, in sliding hernias and in the presence of an undescended testis. Injections are further contra-indicated in the presence of superficial skin infections or erosions caused by the truss, in syphilis, diabetes, senility or marked emaciation. Hernias with a wide ring are not likely to give a good result. A *conditio sine qua non* is a properly applied truss capable of keeping abdominal contents out of the sac at all times. This is frequently impossible in obese patients and in nervous and restless children. The case best suited for the treatment is the small, reducible, indirect inguinal hernia in a young person. The complicated hernias and the large hernias of the middle aged and the elderly are the least suited for the injection treatment. Anatomical conditions in a direct hernia, in the umbilical and the femoral hernia, make the injection treatment undesirable, in the opinion of many.

The treatment as outlined by Harris and White consists of (1) from eight to twelve preliminary injections in a period of one month, (2) four reinforcing injections once a week to consume another month, (3) immediate follow-up examinations once a month for six months (if necessary, occasional reinforcing injections may be made) and (4) final follow-up examinations every two months for one year. The entire treatment requires twenty months for each case. The following are possible complications: an unusually severe local reaction, strangulation, perforation of the bowel, fæcal fistula, peritonitis, abscess, atrophy of the testicle, sexual impotence. The needle may enter a vein or artery. The fluid may be placed too deeply or too superficially. If placed too deeply, it may enter the cord or peritoneal cavity. Injection of the cord results in œdema of the penis, scrotum and epididymis. Such swellings are not uncommon with this method. A certain amount of pain and transient swelling occur,

according to Harris and White, with almost every case. The injection of the fluid into the peritoneal cavity produces an attack characterized by an initial chill and severe abdominal cramps, pain of extraordinary severity in both testes and in the penis, leading to shock. Harris and White state that the fitting and care of trusses require a number of days and careful examination. The treatments themselves are exacting and require skill. The numerous possibilities for dangers and complications make continuous vigilance necessary. 'Even in the hands of competent men, this method may be found unsatisfactory for these reasons'. Harris and White report a recurrence of 4.1 per cent in a follow-up study of 121 completed 'good surgical risk' cases of inguinal hernia. In forty-one cases of inguinal hernia considered a poor surgical risk, their recurrence rate amounted to 19.5 per cent. MacKinney, in a follow-up study of 300 cases, found 83 per cent cured after six months to three and a half years. Rice reported 97.6 per cent cured out of 379 patients after not less than six months. Bratrud, at the University of Minnesota Hospital Clinic, had only nine cases out of a total of 707 in which 'final closure could not be obtained' but states 'I shall be very well pleased if we can keep our recurrences below 10 per cent'.

The statement that the treatment has no fatalities is misleading and unwarranted. Bratrud mentions a case in which 15 minims (1 c.c.) of phenol-thuja solution had been injected into the peritoneal cavity, causing perforation of the ilium and death. Collins observed two fatal cases of pulmonary embolism, a secondary gangrene of the sigmoid and upper rectum, and two complete bowel obstructions resulting from accidental escape of some of the fluid into the peritoneal cavity. Zieman and Larkowski report a case of necrosis of the cord following a single injection of thuja solution.

In striking contrast to the favourable reports of Bratrud, Rice, Harris and White are those of Burdick and Coley reporting from the Hospital for Ruptured and Crippled, in New York. These authors treated ninety-two hernias in sixty-six patients by the injection method. Of fifty-six cases followed up, a definite relapse was noted in forty-seven or 81.03 per cent. At present, eleven patients are apparently cured and nine of these are still wearing trusses. In the face of such disappointing results, they have abandoned the treatment.

Rice states that the end results from this method cannot be accurately adjudged at this time because the results do not extend over a period of more than two years. Bratrud expects not less than 10 per cent of recurrences from the more complicated cases. Fowler states: 'A frank and truthful answer is that as yet we have but little exact and dependable information as to the recurrence rate of the injection treatment'.

Although in the hands of some investigators the results seem to have been good, the complications, the difficulty in selecting suitable cases, and the still uncertain percentage of recurrences would seem to make the method unsuitable except under circumstances in which unusually careful technique and suitable care are possible. Careful follow-up studies for a sufficiently long period will undoubtedly furnish data on which to evaluate it.

Keratoplasty

By R. E. WRIGHT, C.I.E., M.D., Lieut.-Colonel, I.M.S.
(From the *British Medical Journal*, Vol. I, 26th June, 1937, p. 1311)

DURING the last few years much attention has been drawn to corneal grafting by numerous publications in ophthalmological and other journals. The experimental work of Tudor Thomas in England and Cstroviejo in America has illuminated the subject considerably, but has perhaps tended on the whole to emphasize the difficulties of the procedure in the minds of medical men. The demand for the relief afforded by keratoplasty is relatively small in Western countries, and

this, together with the comparative scarcity of good material for transplants, limits the field and tends to make the majority of ophthalmic surgeons in the West hesitate to adopt a measure which presents so many apparent difficulties.

Conditions are different in the Near and Far East, where the demand for relief by corneal grafting is considerable and suitable grafting material is easy to obtain. Under such circumstances it is only to be expected that simplification of technique and greater rapidity of execution should be aimed at and acquired, and although reports of cases and operative detail from Eastern Europe, and India and adjoining areas do not show up prominently in the literature, there is little doubt that in these areas much more practical experience has been obtained in performing corneal grafting on the human subject than elsewhere.

A SIMPLE TECHNIQUE

I am not familiar with the exact methods adopted by the various ophthalmic surgeons who freely employ keratoplasty in the East, but I have evolved a simple technique which appears to hold out as good a chance of success as the more elaborate methods described in recent literature. It has the advantage that it can be undertaken confidently by any ophthalmic surgeon of experience. I demonstrated this method in Melbourne at the Annual Meeting of the British Medical Association, but only on the rabbit, as a patient and donor were not available.

The trephine is used for both graft and bed. The nests of trephines made for me by Messrs. Down Brothers give a fair range in size. Although I have employed a 12-mm. trephine on two occasions my impression is that this is too big, not because the graft does not readily take, but because anterior synechiae are more likely to occur. The formation of an anterior synechia with the back of the graft junction is the complication most to be dreaded in keratoplasty. A 3-mm. trephine is too small except when one employs it for the graft method of treating fistula which I have described. The best average trephine diameter is perhaps 6 mm. There is no real need to have special nests of trephines, although the finish of the edge in specially made cylinders gives a bevel to the margin of graft and trephine hole. Cork borers, such as are found in a laboratory, are almost equally good. No other special instrument is required, although of course it is preferable to use fine needles, such as Barraquer's or Kalt's half circle 7 mm. point to eye (maker's 12 mm.), and a delicate needle-holder such as that made for me by Weiss. The various steps in the procedure are briefly as follows:—

The cornea chosen for grafting should preferably have a normal anterior chamber. (This is highly advisable in earlier attempts. Later, the surgeon may consider what we refer to as reconditioning the anterior chamber before grafting, a much more difficult and tedious procedure.) The graft should for preference be obtained from a living human eye. I have no experience of grafts obtained post mortem. Eyes blind from glaucoma furnish quite good grafts, as do eyes removed in the course of exenteration for malignant disease. It appears to be unnecessary to choose a donor of the correct blood group. The donor and recipient are placed on adjoining tables and prepared in the usual way as regards surgical cleanliness. Akinesia and anaesthesia are established by novocain and adrenalin; pantocaine drops are given. The recipient's pupil should be small, the donor's wide, if this is possible. The necessary instruments for completing the enucleation or exenteration on the donor are left ready and an operator detailed for this work.

PREPARATIONS FOR TRANSPLANTATION

Having decided on the disk diameter and the trephine to be used, the site is demarcated on the recipient's leucomatous cornea by a few rotations of the trephine. The stitches are then put in, taking the first bite at 6 o'clock just off the cornea, where an easy but firm grip can be taken with the point of suture, which does

not produce conjunctival drag or puckering. One end of the thread is held; the needle with the other is carried across the cornea to 12 o'clock, where a similar bite is taken. The needle is then unloaded and the free end carried back to 6 o'clock and laid beside the end already in position. This manoeuvre is repeated at points corresponding to 7.30 and 1.30, 9.30 and 4.30. It is well to do this clockwise and remember the order of placing the sutures. One observes how they will eventually be related to the graft by noting where they cross the demarcated area. The stitches are then pulled free of the demarcated area, the lids closed, and attention given to the donor, who now has a speculum *in situ* and is ready prepared.

TREPHINING THE DONOR

Here the same trephine is used in a corresponding position on the cornea. Good fixation of the globe is desirable. This can be effected simply by a T-shaped fixation forceps. The trephine must be used evenly and freely. It is desirable to go right through and get the disk cut away clean as far as possible. There is generally a hinge left: the shorter this is the better. On removing the trephine the disk opens outwards on its hinge, pushed by the contents of the globe. One should try to avoid damaging the uvea and getting pigment on the graft. If the graft tilts, the hinge is easily cut free on the bevel with fine sharp scissors, either fine blunt-pointed or curved, with one sharp and one beaded point. A fine Stevens type of scissors answers satisfactorily.

If the trephining has been well done the hinge consists of a narrow belt of Descemet's membrane, which is readily cut free. The graft must on no account be touched at this stage except with a camel-hair brush or an equally inoffensive piece of apparatus, and then only on the epithelial aspect. Should the hinge be larger and the graft remain *in situ*, it is perhaps best to complete the separation of the hinge with a narrow Graefe's knife. The knife is plunged through the gap already cut, deep into the eye regardless of the lens, which is dislocated backwards if necessary. The edge is then approximated to the hinge, which is cut on the bevel as the knife is withdrawn. This is repeated. Cutting in the other direction is more dangerous to the graft, and Descemet's membrane is more likely to be rucked up. The severed disk is now received—epithelium downwards—on a Volkmann spoon encouraged by a camel-hair brush. It is submerged in saline—or more elaborate physiological isotonic solution—about body heat. Should vitreous or pigment appear to be adherent to the endothelial face it is gently removed with the brush from the centre towards the periphery. The graft is treated from the beginning like a delicate histological section in process of mounting. The donor is then left to another surgeon and the process of trephining the recipient commenced.

TREPHINING THE RECIPIENT

Here one must proceed with great caution. With even rotation, trephine as far through the cornea as possible; it is generally fairly obvious when one is nearly through. A slight tilt is then given to the trephine, which goes through followed by an aqueous escape. In this case the hinge is likely to be much larger, possibly two-thirds the circumference of the circle. Fortunately one can seize the disk in a forceps and deliberately sever the hinge slowly and carefully with a suitable bevel by means of the knife or scissors, such as mentioned above. The chamber is now inspected. Let us assume the pupil is contracted, the iris intact, and the lens clear. This is the ideal background. A little normal saline is run in from the irrigator. This temporarily gives a view towards the angle and leaves a little fluid between iris and cornea.

THE TRANSPLANTATION

The graft is now lifted with the Volkmann spoon and camel-hair brush from its warm saline, tumbled into the aperture, and adjusted to its new position by

a few touches of the brush. The stitches are then replaced over it in their order and tied off by means of a pair of forceps suitable for the purpose. Suture-tying forceps are most desirable at this stage, and Silcock's iris forceps are more useful for this than the purpose for which they were originally intended. Atropine and iodoform ointment is now placed in the conjunctival sac, the eye closed, and both eyes bandaged. The patient is kept somewhat quieter than a cataract case, gently examined on the third day, and a little more atropine and iodoform ointment given. The graft has usually taken by this time and the chamber formed. On the fifth day the stitches are removed. Atropine is continued. The patient is allowed to walk to inspection and goggles are given on the eighth day.

POINTS OF GENERAL INTEREST

It is undesirable here to go into all the variations that may have to be adopted if the condition of the recipient's eye is other than that suggested above—for instance, in leucoma adherens with shallow or non-existent anterior chamber and the whole gamut of abnormal conditions in the anterior segment which follow gross corneal ulceration. The procedure of preliminary investigation and preparation naturally varies in every case, but its detailed discussion is more suited to a thesis on corneal plastic methods. There are a few points of general interest and practical importance which may be noted here:

A cornea that has previously been vascularized—for example, one which has been affected by interstitial keratitis or trachomatous pannus—offers better soil for a graft than a cornea free of such old vessels. This has been known for a long time, and is referred to by Elnsnig.

A child is a much more difficult subject for keratoplasty than an adult.

It is important to respect Descemet's membrane; it readily lifts, buckles, and detaches at the cut edge.

Anterior synechiae are liable to form in this situation. These are almost certain to be followed by opacification of the graft unless very trivial and freed early. The use of eserine is preferable to that of atropine in the grafted eye if the graft is large. Atropine may be desirable if the graft is small; this requires judgment. The main object is to avoid anterior synechiae.

The stitches must not be left too long; they may damage the graft: five days is quite long enough. An optimum result with a clear graft and really good visual acuity is exceptional. Improvement to the extent of allowing a previously 'led' patient to see large objects and get about alone is a modest expectation in straightforward cases. Patients must be warned not to expect too much; this saves disappointment. The most theatrical effects are produced by successful keratoplasty when the blind patient is made to see, but this is by no means the only indication for corneal grafting. As a method of repair it is often far superior to the conjunctival flap, the epithelial graft, and such plastic procedures.

The Early Diagnosis and Treatment of Abdominal Tuberculosis

By R. LIGHTWOOD, M.D., F.R.C.P.

(Abstracted from the *Practitioner*, Vol. CXXXIX, November 1937, p. 535)

CLINICAL FORMS

BEYOND question abdominal tuberculosis, even more than other forms of tuberculosis, is declining, and this is the result of the increasing pasteurization of milk. The symptoms of abdominal tuberculosis are indeed becoming quite uncommon, though paradoxically caseous or calcified mesenteric glands are still often found at operation and autopsy. Evidently there is much symptomless abdominal tuberculosis. In spite of the comparative rarity of clinically manifest abdominal tuberculosis the disease is often suspected and nearly as often wrongly diagnosed on insufficient data.

If abdominal symptoms arouse suspicion, a tuberculin reaction should be performed. The intradermal test (Mantoux) using 0.1 c.cm. of a 1 in 1,000 dilution of old tuberculin may be employed. A negative reaction for all practical purposes excludes the diagnosis. A positive reaction should lead to a search for other confirmatory evidence.

Tuberculous enteritis.—If a tuberculous ulcer forms the onset of symptoms is likely to be insidious. The symptoms may be pain, loss of weight and diarrhoea. Occasionally the stools may contain a little pus or blood but this is seldom manifest. Confirmation of the diagnosis may be obtained by having the stools examined for tubercle bacilli. Fever may be present together with other general signs of infection. Examination of the abdomen shows it to be tumid, somewhat resistant and diffusely tender.

Tuberculous adenitis.—This must be a common condition, yet most cases pass unnoticed so inconspicuous are its symptoms and signs. The outstanding sign is the detection by palpation of enlarged glands in a child with a positive tuberculin reaction. Their differential diagnosis requires the exclusion of the possibility that the masses may be faecal. This possibility can be settled by watching the effect of warm olive-oil enemas. Among the general symptoms of *tuberculosis mesenterica* are abdominal pain (which may give rise to suspicion of appendicitis), slight fever, stationary weight and irregularity of the bowels.

Tuberculous peritonitis.—This is becoming more and more rare. The two chief varieties, the ascitic and the plastic, are so well described in all textbooks that they do not require description here. Ascites in a child whose tuberculin reaction is positive is most likely to be due to tuberculosis. In the plastic form of peritonitis an omental tumour often forms across the upper part of the abdomen and masses may be felt in other situations. Sometimes a tuberculous abdominal mass may be confused with a chronic intussusception. When this difficulty arises Still's sign may be invaluable: the tumour which forms in intussusception shows peristaltic contractions, tuberculous masses do not. An opaque enema may also be of the greatest diagnostic value.

Radiological assistance in the diagnosis of tuberculosis of abdominal glands can only give help in a healing stage, i.e., when calcification has begun. If a child with abdominal glands and a positive tuberculin reaction is x-rayed and calcification is visible a good prognosis may be given, because the fact that the glands are visible indicate that healing has been effected or is taking place.

TREATMENT

Estimations of the sedimentation rate are chiefly of value in following the course of a patient under treatment. Complete rest will be required until some weeks after all the signs of activity have passed away. The signs of activity are failure to gain in weight, fever, sweating, abdominal enlargement (and ascites) and a raised sedimentation rate.

The essentials of treatment are complete rest, proper feeding and open air. The severity of the condition determines to what extent rest must be enforced. In the more acute and severe cases the legs as well as the abdomen must be immobilized and a plaster bed is useful for doing this. Other less severe cases can be in bed without special apparatus. Feeding should be sufficient to enable the child to put on weight but it is not wise to recommend 'stuffing'. Anything which increases peristaltic activity of the bowel must be excluded. Hence parents are told to exclude brown bread, porridge unless sieved (and any other of the fancy breakfast cereals), raw fruit and stewed fruit unless sieved, and all green vegetables unless sieved. All jams with pips and skins must be omitted and other articles of dietary such as salad which tend to leave a residue. The diet should mainly consist of dairy produce (milk, eggs, butter, cream, cheese) for its calcium content. Well-cooked milk puddings and good home-made soups are also excellent. There is a theoretical objection to these high-fat diets on the

ground that the lacteals may be blocked, but in practice, unless the stools do become fatty there is no need to reduce the fat content of the diet. Except for vitamins drug treatment plays a minor part. Preparations containing vitamins A, D and C are especially indicated. Salts of calcium may be used in the healing stages to ensure that there is sufficient of this mineral to effect calcification of the glandular lesions. Useful preparations are:—dicalcium phosphate 20 to 30 grains t.d.s., calcivitan (Richter) one tablespoon daily and calcydic (A. and H.) one or two teaspoonsfuls. These preparations should be taken before meals. Liquid paraffin should be given to regulate the bowels and in obstinate cases warm olive-oil enemas may be necessary.

The question of surgical treatment must be briefly discussed. The resemblance of appendicitis to inflamed mesenteric glands is often close and some hold the view that the appendix should be removed in all cases. This is probably too radical, but if the pain is severe, causing vomiting and associated with loss of weight, then laparotomy may be called for, with removal of the appendix and any other obvious focus, such as a tuberculous Fallopian tube. In the ascitic form of tuberculous peritonitis a laparotomy can be employed to evacuate a fluid of low bactericidal power in the hope that it will be replaced temporarily by a serous effusion of higher bactericidal power. It is undoubtedly true that many children with free fluid show improvement from the time of the laparotomy, but on the other hand it is just in the early ascitic type of the disease that general hygienic measures secure the best results. One advantage of laparotomy is that it does enable the diagnosis to be established beyond all shadow of doubt and it also confirms an opportunity for removal of the appendix which some authorities regard as the essential primary focus in almost all forms of abdominal tuberculosis. In any case surgical intervention must be followed by rest under good hygienic conditions, a generous diet and, if available, sunlight. It is possible that the after-treatment is more responsible for good results than the surgical episode.

Bug Destruction

(From the *British Medical Journal*, 22nd January, 1938, Vol. I, p. 177)

THE bed bug is not normally a vector of communicable disease, but everything else that can be said of it in its human relations is by way of dispraise. By means of its powerful beak it pierces the skin of man, raising a painful red blotch surrounded by papules. By means of a pair of glands situated in its thorax it diffuses a repulsive odour. It is a pest in houses, lying concealed by day in cracks and crevices and emerging at night to suck the blood of sleepers. The presence of bugs in dwellings, besides being vexatious to tenants, has also come to carry some suggestion of a social stigma, and quite a range of substances of varying degrees of activity has been employed from time to time for their extirpation. Turpentine and scalding water, corrosive sublimate and painters' blow-lamps, naphthalene and sulphur dioxide have all been applied without conspicuous success, and so recourse has been had, as a last resort, to gaseous hydrocyanic acid.

While fumigation with hydrocyanic acid has been found quite effective for the destruction of bugs, the method completely fails to conform to the requirement that a convenient disinfectant should not be unreasonably toxic to man, by attacking operators or dwellers in adjacent premises or by leaking out of stuffed furniture after the fumigation is over. When the acid is employed for killing rats in the holds of ships the whole procedure can be kept under strict control, but its routine use about people's homes for the destruction of insects, even granted that bugs are a pest and that all precautions are taken, as we believe they are, conveys to the mind a suggestion of incongruity between the risks taken and the results achieved. A

report in this number of the *Journal* suggests that the vapour of heavy naphtha may be found on extended trial to possess a bug-destroying power which is for practical purposes equal to that of hydrocyanic acid while at the same time non-toxic to man. The method recommended is to spray the naphtha on the surfaces to be disinfected and also on sheets of Egyptian cotton hung on frames of electrical conduit tubing three inches from the walls, with a view to producing a concentration of naphtha vapour in the air of the room. The room is then sealed and kept sealed for twenty-four hours. Just before sealing up the room a clockwork-driven delayed-action naphtha sprinkler is placed in position and set to deliver a reinforcing charge of naphtha from nine to eleven hours later. This is done in order to ensure that naphtha vapour remains in the air in lethal concentration. When the room is unsealed all bugs should be dead. Lethal concentrations of naphtha for bugs are from 0.15 per cent upwards, with twenty-four hours' exposure. It is

important that the room temperature should not fall below 50°F., and preferably that it should be 60°F. or over. Owing to the rapid escape of heat from houses, rooms for disinfection in winter should be raised to 80°F. before the process begins. As the flash point of the naphtha is 105°F. no naked lights or tobacco smoking can be permitted. The only instance of disability among the workmen employed on the tests was one case of irritation of the skin of the hand, which readily yielded to lanoline. With suitable modifications the method can be applied to empty or furnished rooms or vans containing furniture.

On weighing up the results of the tests which have been carried out the impression is distinctly favourable to the tentative claims made on behalf of heavy naphtha. The reporters have rendered a useful service by their work with the substance. If bugs can be killed with ease and precision by its means there will be no need for operators or others to incur the major hazard of hydrocyanic acid.

Reviews

DIE MALARIA: EINE EINFÜHRUNG IN IHRE

KLINIK, PARASITOLOGIE UND BEKÄMPFUNG.

Von:—Professor B. Nocht, Dr. Med., Dr. Med., H. C. Hamburg, und Professor M. Mayer, Dr. Med., Dr. Med. vet H. C. Hamburg. 1936. Verlag von Julius Springer, Berlin. Pp. 172. Mit 24 Abbildungen und 2 Farbigen Tafeln. Price, RM: 15.60.

MALARIA: A HANDBOOK OF TREATMENT, PARASITOLOGY AND PREVENTION.—By Bernard Nocht, M.D., and Martin Mayer, M.D. 1937. John Bale, London. Pp. viii plus 196. Illustrated. Price, 10s. 6d.

The first German edition of this work was published in 1918, and, though it was well received by the medical profession, it was the second edition of 1936 that attracted more universal attention, and those who were unable to get the best out of the book on account of their limited knowledge of the language have looked forward to the inevitable English translation ever since.

Bernard Nocht, the 'grand old man' of tropical medicine who has recently celebrated his 80th birthday, was for many years director of the Tropical Diseases Institute at Hamburg, and has always been especially interested in malaria and blackwater fever; his views on the subject have always been sound and have carried considerable weight everywhere. Similarly, Martin Mayer is well known for his work in the tropical field and as a teacher at the Hamburg institute, he has contributed much to our knowledge of both malaria and leishmaniasis. Much was therefore expected from their collaboration and we believe that few readers will be disappointed.

Although the book is a small one, the subject has been dealt with comprehensively and all aspects of the malaria problem are touched upon, from the history of the disease to its control by the destruction of larvæ and adult mosquitoes. Some of the major section headings are 'clinical picture', 'treatment', 'blackwater fever', 'induced malaria therapy', 'medicinal individual prophylaxis', 'determination of malaria index of population', 'technique of blood examination', 'zoology' and 'the carriers of malaria'.

The introduction of the synthetic anti-malarials has of course entirely revolutionized treatment and the section in this edition bears little resemblance to that in the original 1918 edition. Quinine, atabrin, plasmochin and the combinations of these drugs, more especially quino-plasmochin, are discussed separately. The place of arsenic also is considered. A short summary of the various methods of treatment is given: this makes comparison of the different drugs easy. It is, however, a little unfair to quinine to recommend the prolonged

6-weeks' course of this drug and only a 7-days' course of atabrin. The general opinion to-day is, in any case, against the prolonged administration of any anti-malarial drug, except in cases where reinfection is likely, or as a prophylactic measure.

The sections on technique should be very helpful and there are some quite useful coloured plates.

There is a formidable list of errata in the English edition and many of the page headings are singularly inappropriate, e.g., 'anæmia' on page 83 and 'blood regeneration' on page 125: the printer appears to have adopted the 'shut-eyes-and-pin' method for making his choice for these page headings.

This book is a very welcome addition to the literature on malaria and we can strongly recommend it to all engaged in the struggle against this disease, whether they be sanitarians or physicians.

L. E. N.

THE PRACTITIONERS' LIBRARY OF MEDICINE AND SURGERY. VOLUME XIII, SUPPLEMENT AND INDEX. 1938. D. Appleton-Century Company, Inc., New York and London. Pp. xiii plus 1161. Illustrated. Complete in 12 volumes and general index. Sold in complete sets only. Rs. 485. Only available from Messrs. Butterworth and Company (India), Limited, Calcutta

SUBSCRIBERS to this very important American publication will feel that they are getting something for nothing. They were promised twelve volumes and an index; in the present volume they have been given an index of 350 pages and in addition 808 pages of supplement. The first volume of the series bore the date of 1932 and in the medical world things have happened during the intervening years; many of these happenings are recorded in this supplementary volume, which is in fact a kind of medical quinquennial. Even in a well-planned work omissions are inevitable and such omissions as were discovered have been made good also in the present volume.

There is an excellent account of calcinosis with a number of good illustrations: this is an example of an earlier omission. Another example is sandfly fever: the account given of this is one of the best in medical literature. There is additional matter on the typhus group of fevers. The classification given is dependent on the Weil-Felix reaction; this is a very unsatisfactory classification as it takes us no nearer the solution of the ætiology of the members of this group in which it is obscure, as for example, Indian tropical typhus. The Weil-Felix reaction is not a truly specific reaction, but is due to a curious accident in the similarity to one another of the antigenic structure of two genetically unrelated organisms. Further, we cannot agree that

all the types included in the third group of this classification give a positive Weil-Felix reaction to all three strains.

The writer does not seem to have made any reference to the initial lesion, the *tâche noire*, of eruptive Mediterranean fever, also called *fièvre boutonneuse*, a name which itself suggests more than the ordinary macular typhus rash.

There is a useful article on habitual hyperthermia: in a country where the word *fever* is used as a synonym for *illness*, it is important to realize that about one per cent of individuals have a normal temperature as high as 99.7°F.; remembering this simple fact may save many patients being torn to pieces in a search for a supposed septic focus and in the process losing their teeth, tonsils and even cervix uteri, or being poisoned with overdoses of carbarsone, sulphanilamide, or quinine, when a better result would have been achieved by removing their clinical thermometers.

There are articles on mandelic acid, in urinary sepsis, on diabetes, protamine insulin, and ergotamine in migraine, but the only reference in the index (which incidentally is not above criticism) to sulphanilamide is to 'sulfanilamide poisoning'. The subject of sexual impotence in men has been given a number of pages; the writer explodes a number of fallacies.

A single volume of this work weighs 6½ pounds; we were therefore looking forward to a lighter general index, but the present volume is probably the heaviest of the thirteen and it needs quite strong wrists to remove it from the shelf; though it may sound ungrateful, when the publishers have added this excellent supplement without adding to the price of the whole series, we are sorry that the general index could not have been bound separately.

It is a little late to suggest to our readers that they now become subscribers to this very valuable work, but it is quite possible that there are still some sets available. We can congratulate the editors, the contributors, and the publishers on the successful achievement of a very ambitious undertaking.

PHYSIOLOGICAL CHEMISTRY OF THE BILE.—By H. Sobotka. 1937. Baillière, Tindall and Cox, London. Pp. xii plus 202. Illustrated. Price, 13s. 6d.

In this volume the author has endeavoured to gather together from the voluminous literature, the data with regard to the physiological, pharmacological and pathological aspects of bile acids and other chemical constituents of bile. Bile is a highly complex fluid and the physiological significance of many of its constituents is unknown. In order to understand the function of an organ it is essential to have a knowledge of its structure. The author therefore follows the plan of preceding the account of physiology by a short description of anatomy of the biliary tract, its histology and the cytology of the bile. In the chapters which follow, the biochemistry of bile and its various constituents, the influence of the various chemical, physical and biological factors on the biliary secretion and the effects of bile acids on the organism are dealt with in detail. The author has made brief comments himself in many places with a view to bringing out the significance of the liver as a secretory organ, whose physiological activities are very important in the economy of the body.

The book is well written and will be of great interest to those interested in this subject. Its value is greatly enhanced by a very comprehensive and well-arranged bibliography and authors' index which run to 50 pages.

R. N. C.

PRACTICAL TALKS ON KIDNEY DISEASE.—By E. Weiss, M.D. Baillière, Tindall and Cox, London. Pp. xii plus 176. Illustrated. Price, 9s.

This volume contains a critical though concise survey of our knowledge of kidney disease, emphasizing the practical aspects of this important subject. Tribute is paid to the monumental work of Richard Bright and the author has referred to many of the well-known

recent contributions. In the first few chapters the physiology and pathology of the kidneys, and the various types of nephritis are dealt with in detail, and valuable hints are given with regard to treatment. The author emphasizes the inadequacy of the clinical significance of the term 'nephrosis' and leans towards the conception that nephrosis is a term which should designate a degenerative lesion confined to the kidney tubules. Dealing with the relation of hypertensive vascular disease to kidney disease, the author considers that arteriosclerosis with renal manifestations can best be explained by assuming that arteriolar involvement ante-dates the renal changes and that nephritis is either a result of the vascular changes or due to the same cause which produces an abnormal condition of the arterioles. Hypertensive vascular disease is said to be responsible for 25 per cent of all deaths of persons over 50 years of age. The cause of essential hypertension is admitted to be unknown, but, in its treatment, a regime of reduction of proteins, no tobacco, rest and no drugs are suggested.

The book will certainly prove very useful to the medical profession as it gives a clear conception of kidney disease and treatment of hypertension.

R. N. C.

THE COLLAPSE THERAPY OF PULMONARY TUBERCULOSIS.—By John Alexander, B.S., M.A., M.D., F.A.C.S. 1937. Baillière, Tindall and Cox, London. Pp. xiii. plus 705. with 367 figures. Price, 67s. 6d.

THE collapse therapy of pulmonary tuberculosis constitutes the greatest advance in recent years for cases in which the course of the disease is progressive in spite of ordinary treatment. The choice of the most suitable of the available operations for a particular patient presents however a complex problem which can only be solved by a sound knowledge of the action, advantages, and disadvantages of each operation.

Dr. Alexander's book seems to fulfil the purpose. It is based upon an experience with the surgical treatment of about eighteen hundred patients and various observations by the author and other contributors. In addition to the value of roentgenograms, the importance of due consideration of the patient's age, general and cardio-respiratory condition, pulmonary lesion and many other variable factors has been stressed as essential before a decision as to the proper form of treatment can be made. Ten different operations which may be used singly or in various combinations have been described; of these pneumothorax, phrenic paralysis and most often practised, while operations , pneumolysis, cavity drainage, etc., are used to extend the benefit of collapse therapy. The operative technique and pre- and post-operative management have been fully described, the good and bad points of each procedure pointed out, and the inter-relationships of various operations mentioned. The concluding remarks in almost every section are very useful.

Two chapters on the physiological principles and the pathology of pulmonary collapse have been contributed by Dr. Pinner, two chapters on pneumothorax by Dr. Branwell, and a chapter on oleothorax by Dr. Howlett, Jr. The last two chapters of the book deal with tuberculous empyema and tuberculosis of the thoracic wall.

The book is rather too big for its subject, and, as is not unusual in books written by different authors, there is a certain amount of overlapping, as for instance the definition of collapse therapy and some descriptions have been repeated in several places, though in a different way.

The illustrations are profuse and vivid. The photographs of eighteen pioneers in collapse therapy are of great historical interest. A bibliography of 1,342 references has been given at the end of the book. The get-up of the volume is excellent. The book will be useful to those interested in the surgery of pulmonary tuberculosis.

R. C.

MODERN ADVANCES FOR RURAL PRACTICE.—By P. C. Dutta, M.B. (Cal.), F.R.C.S. (Edin.), D.G.O. (Dub.), Capt., I.M.S. 1938. Messrs. Butterworth and Company (India), Limited, Calcutta. Pp. 174. Illustrated. Price, Rs. 3-8.

THE book is primarily meant for the rural practitioners but the author hopes it will prove equally useful to the average general practitioner in India, who has not the modern methods of diagnosis and treatment at his disposal. In compiling the book he has endeavoured, as far as possible, to keep strictly to the essentials of treatment, avoiding unnecessary descriptions and details for which the busy practitioners have no time. The diseases have been arranged alphabetically to facilitate easy reference.

One fails to see what constitutes in this book a special feature for rural practice. It deals with agranulocytosis, myasthenia gravis and Addison's disease, but not the diseases or conditions such as tropical splenomegaly, hepatic cirrhosis, cancerum oris, ascariis infection, heat fever, etc., which the practitioner will encounter daily.

The treatment advocated for certain conditions is difficult to justify, for instance, injections of quinine hydrochloride in blackwater fever and of liver extract in smallpox, the administration of a liberal diet in hæmatemesis, and the application of egnolin in oriental sore. There is confusion in the description of the anæmias, and both sprue and cerebro-spinal fever have been dealt with very inadequately.

On the whole the book will be found very useful, as it contains much valuable information. The illustrations of the hand infections, tables of infant feeding and food values are useful.

R. C.

FRACTURES AND DISLOCATIONS FOR PRACTITIONERS.—By E. O. Geckeler, M.D. 1937. Baillière, Tindall and Cox, London. Pp. x plus 252, with 213 illustrations. Price, 18s.

It has to be admitted that there is no dearth of excellent textbooks on the subject of fractures and dislocations. A newcomer is, therefore, liable to meet with a critical review unless it has some special features to offer. This book, which has been written for the benefit of the general practitioner, aims at presenting the surgery of fractures and dislocations in a condensed form without the omission of important details. On account of the increasing frequency and severity of street accidents, the responsibility of general practitioners is considerably increased, since they have to undertake efficient first aid if not the entire treatment of these cases. The object of the author, therefore, is a laudable one.

This book consists of two parts of which the first, comprising 19 chapters and 202 pages, deals with the subject of fractures. The smaller and second part, dealing with dislocations, consists of only 46 pages and 13 chapters. The consideration of the subject-matter will be found satisfactory on the whole, but there are some shortcomings which must be mentioned. With regard to skeletal traction, there are full descriptions of the archaic methods for the insertion of Steinmann's pin and the ice-tongs. There is only a brief reference to Kirschner's wire and it has not been favoured even with a single illustration, although there are 213 pictures in the book. The requisition of the surgeon's heel, for the reduction of certain fractures and dislocations, may be regarded as a thing of the past. There are at least three pictures depicting this method. We are also in doubt if it is right to expect the general practitioner to undertake the operative treatment of patella fractures or the insertion of the Smith-Petersen nail in fractures of the neck of the femur.

This book is not without its merits. The importance of after-care for restoration of function has been well emphasized. The reproduction of the x-ray plates is very good and the techniques of manipulation are also clearly set out. We hope that this book will be of some

value to the general practitioner. The printing and get-up are excellent and there is a useful index.

P. N. R.

THE THERAPEUTIC PROBLEM IN BOWEL OBSTRUCTIONS: A PHYSIOLOGICAL AND CLINICAL CONSIDERATION.—By O. H. Wangensteen, B.A., M.D., Ph.D. 1937. Baillière, Tindall and Cox, London. Pp. xxi plus 360, with 90 figures. Price, 27s.

THIS book forms a well-balanced contribution to surgical literature, bringing together for the first time the voluminous but widely-scattered published work on a subject in which advances of knowledge are fast being contributed from all parts of the world.

There are three parts to the book. The first, embodying as it does the Samuel D. Gross Prize Essay for 1935 of the Philadelphia Academy of Surgery, sets a very high standard which is sustained throughout the remainder of the book. The basis of the work is the experimental work carried out by Wangensteen himself, either original or in confirmation of the work of some other experimentalist. The approach to each point or problem is always physiological. In spite of the highly scientific nature of the work, the facts are presented in a concise and eminently readable manner.

It would be quite impossible to pick out any one part of this work as being of greater note or value than the remainder.

Surgeons young and old should welcome this work from the laboratory of a well-known American authority on bowel obstruction. There are chapters which should be read by house surgeons and senior students. Those interested in the problem of bowel obstruction will doubtless equip themselves with this book, but it should be read by all interested in the advance of surgery.

The author and the publishers are to be congratulated on the excellence of their production.

A. T. A.

THE PROGNOSIS IN SCHIZOPHRENIA AND THE FACTORS INFLUENCING THE COURSE OF THE DISEASE. A KATAMNESTIC STUDY, INCLUDING INDIVIDUAL RE-EXAMINATION IN 1936 WITH SOME CONSIDERATIONS REGARDING DIAGNOSIS, PATHOGENESIS AND THERAPY.—By G. Langfeldt, M.D. 1937. Oxford University Press, London. Humphrey Milford. Pp. 228. Obtainable from the Oxford University Press, Bombay and Calcutta. Price, 12s.

THIS brochure of Dr. Langfeldt is a very important contribution to the recent literature on schizophrenia, a disorder which is now receiving more and more attention the world over. As the title of the brochure proclaims, the primary object of the author is to elucidate the question of prognosis, but he has a good deal to say besides about the pre-psychotic and other factors which may be considered likely to influence the prognosis. First and foremost, Dr. Langfeldt is convinced that many of the complaints usually described as schizophrenia represent a congeries of diseases differing widely in their pathogenesis.

He divides these so-called schizophrenias into two main divisions, the typical schizophrenias and what he terms atypical schizophreniform psychoses. The first group, which Dr. Langfeldt would prefer to see called schizophrenic process psychoses, is characterized by very pronounced symptoms and by a poor prognosis and may be conveniently considered under three sub-heads namely: (1) the primary persecution dementia, (2) a type characterized by a loss of the sense of reality with delusions of reference, and (3) the typical katonic form of schizophrenia. Transitional forms do occur. In regard to the pathogenesis of these three groups, the author believes that the morbidity of the first type lies in the phylogenetically youngest parts of the brain while the morbidity of the other two forms may be sought in the phylogenetically older parts of the brain. Indeed, the typical katatonia is probably associated with disturbances in the middle brain.

The author's view of the localization of the schizophrenias in different cortical and subcortical strata is supported, *inter alia*, by his observations during insulin treatment. For example, he states that insulin cannot effect a cure in the typical schizophrenias, although 70 per cent cures are claimed among the atypical schizophrenias, disorders which will as frequently recover in 6 or 12 months without this dangerous treatment.

With regard to the factors influencing the course of the disease, the author maintains that the inheritance of insanity does not seem to have any decisive influence on the prognosis. Indeed, it seems that the occurrence of insanity in direct ascending or collateral lines may be quite a favourable factor. As regards bodily constitution and temperament, a pronounced schizothymic or schizoid temperament seems to be a prognostically unfavourable factor, whereas the so-called pyknic constitution is favourable from the standpoint of prognosis.

In respect to the intellectual ability of patients, the author has observed that those who had good school records are more liable to form antisthetic hyper-aesthetic reactions. It is a great pity that this extremely interesting and important piece of work should be marred in places by the mis-spelling of English terms. For example, such words as 'subcortical', 'manodepressive', 'stomache', 'schizotyme', 'cyklotyme', and so on. The author uses the term 'delirium' in the French sense of the word *délire* and the word 'casuistry' to denote the expression 'case history'.

O. B-H.

PAPERS ON PSYCHO-ANALYSIS.—By E. Jones, M.D., M.R.C.P. (Lond.). Fourth Edition. 1938. Baillière, Tindall and Cox, London. Pp. x plus 643. Price, 25s.

EVERYONE who takes an interest in psycho-analysis will welcome this latest edition of Dr. Ernest Jones' masterpiece. As he states in the preface, this book started twenty-six years ago and has since become 'a slow-moving picture of the development of psycho-analysis'. The present volume has twelve new essays added to it while twenty older ones have been taken out to make room for them. Of the new additions, Dr. Jones' paper on 'jealousy' is one of the most striking. Besides an unusually good index, the book contains a copious glossary. It is to be hoped that this new edition will stimulate Indians in psycho-analysis for up to the present practitioners and students of psycho-analysis are almost entirely Bengalees.

O. B-H.

THEORETICAL PRINCIPLES OF ROENTGEN THERAPY.—Edited by E. A. Pohle, M.D., Ph.D., F.A.C.R. 1938. Henry Kimpton, London. Pp. 271. Illustrated with 132 engravings. Price, 21s.

THIS volume on the theoretical principles of roentgen therapy, which is going to be followed by a second on the more clinical aspects of radiation therapy, bears the stamp of authority. Each section is written by an acknowledged leader in the particular field covered, the contributors being:—R. R. Newell, M.D., Professor of Medicine (Radiology), in the Stanford University Medical School, San Francisco, California; Ernst A. Pohle, M.D., Ph.D., Professor of Radiology, in the University of Wisconsin, Madison, Wis.; K. Wilhelm Stenstrom, Ph.D., Professor of Biophysics in the University of Minnesota Medical School, Minneapolis, Minn.; Lauriston S. Taylor, Ph.D., Physicist, Bureau of Standards, Washington, D.C.; Francis Carter Wood, M.D., Director, Institute of Cancer Research, in the Columbia University, New York City.

The work is divided into five chapters. The first of these on the physics of the roentgen ray, is written by Dr. K. W. Stenstrom. This section is extremely concise, and forms lucid exposition of a difficult subject. The measurement of α -radiation has become increasingly accurate within the last few years, and a description of the various methods will be easily

understood by anybody with even a meagre knowledge of physics.

The second chapter on apparatus is dealt with by Dr. R. R. Newell, and contains descriptions including the most modern high voltage plants.

Dosimetry is dealt with by Drs. Lauriston Taylor and E. A. Pohle, who have dealt with the subject in a thoroughly practical manner.

The fourth and extremely important chapter by Dr. F. C. Wood deals with radiobiology and radiopathology. This is by a long way the best account within the compass that has appeared on this rapidly changing subject. The last chapter by Dr. Lauriston Taylor deals with protection from roentgen rays.

This work will be welcomed by radiologist and clinician alike.

G. G.

EYE STRAIN AND CONVERGENCE.—By N. A. Stutterheim, M.D. (Rand.). 1937. H. K. Lewis and Company, Limited, London. Pp. x plus 89. Price, 7s. 6d.

THIS monograph deals with the author's views in the ætiology and treatment of 'eye strain'. The exact pathology of 'eye strain' is still unknown, but the author's opinion is that the cause is due to weakness of convergence. He points out that 'errors of refraction' may implicate eye strain, but they are never the true cause of it. Many people without appreciable ametropia have eye strain, and often in a severe form, and people with high ametropia as a rule have very little eye strain. Eye strain is certainly not due to weakness of the eye, or eyes, and is prevalent in visually strong, healthy, nearly emmetropic, slight hypermetropic, or slightly astigmatic eyes.

The author discusses defective power of convergence from the anatomical, physiological, clinical and therapeutic aspects. He makes out a good case that this is its principal cause and gives a lucid description of his methods of treatment and the very satisfactory results he has obtained. He pleads that schools of ophthalmology should return to physiological methods in the treatment of eye strain and that it can be cured by kinetic treatment which is designed to unfold the power of convergence. The book is a valuable contribution to ophthalmic literature, will be read with great interest and will be found most useful to ophthalmic surgeons practising in India.

E. O'G. K.

A PRACTICAL GUIDE IN THE TREATMENT OF EYE DISEASES (OPERATIVE AND MEDICINAL).—By K. Krishna Murty. 1937. Published by Dr. Krishna Murty, L. N. Hospital, Chodavaram, South India. Pp. 86. Illustrated. Price, Rs. 2.

THIS small book is written with a view to engaging the attention of general medical practitioners to face the problem of ever-increasing blindness in India. The author is not successful in achieving that end in view, with his limited resources.

The book is divided mainly into two portions, the first part dealing with the operative treatment and the other with the therapeutics of the various eye diseases. Some of the common operations on the eyes are described elaborately, mentioning the common complications which may arise during the course of operations. Synopses for the treatment of the ocular diseases are considered to be of little practical value to general practitioners or post-graduates.

A number of printing mistakes have crept in. The general get-up of the book should be improved.

E. O'G. K.

OCCUPATIONAL THERAPY: AN ADDENDUM TO THE HANDBOOK FOR MENTAL NURSES. 1938. Published for the Royal Medico-Psychological Association. Baillière, Tindall and Cox, London. Pp. 16. Price, 6d.

THIS brochure is exceedingly concise and yet fully informative in regard to the value of occupation as a

therapeutic agent for persons suffering from mental disorders. For some reason or another, it does not seem to have occurred to the author that occupation is potent as regards the therapy of any illness, a fact long ago discovered and put into practice in the U. S. A., where an occupational therapy association has existed for many years, thanks to the unremitting enthusiasm of Mr. E. Slagle, its president.

On page 11 the author gives two lists of occupations, one set for men and another for women. There is no point at all in this. Some women take very kindly to work usually allotted to men, and, perhaps what is even more unusual, men often like to occupy themselves with work ordinarily undertaken by women. The

psychological basis of allotting occupation to a mentally disordered patient should be, as far as possible, in some way related to the psychogenesis of the disorder. It is a great mistake to insist, as the author suggests, that what patients make should conform to normal standards. Many paranoiacs will get deeply engrossed in the construction of all sorts of more-or-less useless 'contraptions'. It is fundamentally wrong to urge them to do otherwise. Many readers of this brochure are likely to imagine that William Tuke, whom the author rightly cites as a reformer in the care and treatment of the insane, was a doctor. He was not: He was a tea-broker of the Society of Friends.

O. B-H.

Abstracts from Reports

ANNUAL REPORT OF THE CHEMICAL EXAMINER'S DEPARTMENT, MADRAS, FOR THE YEAR 1936

THE total work of the department does not show any appreciable decrease as compared with previous years in spite of the transfer of a portion of this Presidency to the new Orissa Province.

HUMAN POISONING CASES

The total number of human poisoning cases examined during the year was 363 with 2,090 articles as against 380 cases with 2,341 articles in 1935 and 327 cases with 1,995 articles during 1934.

Poison was detected in 185 cases or 51 per cent.

The nature of the poisons detected is shown in the following table:—

Poisons detected			Cases
Inorganic poisons			
Arsenic	12
Arsenic and copper	1
Arsenic and mercury	2
Arsenic, copper, mercury and aconitine	1
Copper sulphate	12
Cyanide	7
Cyanide and alcohol	1
Mercury	9
Mercury and copper	2
Mercury and oleander	1
Mercury and unidentified	1
Nitric acid or nitrates	9
Potassium or sodium nitrite	2
Potassium permanganate	1
Sulphuric acid	1
Sulphuric acid and nitric acid	1
Total			63
Organic poisons			
			Cases
Aconitine	5
Alcohol	6
Bamboo shoots	1
Cresols	2
Croton seeds	1
<i>Gloriosa superba</i>	4
<i>Jatropha curcas</i>	1
Kerosene oil	2
Madar	14
Datura or mydriatic alkaloid	11
Nux vomica or its alkaloids	4
Oduvan	2
Oleander	28
Opium	31
Phenol and aconitine	1
Turpentine	1
Unidentified	8
Total			122

Opium heads the list with 31 cases closely followed by oleander with 28 cases. There has been a decrease in cases of datura or mydriatic alkaloid poisoning, 11 cases in 1936 as against 20 cases in 1935. There has been an increase in cases of poisoning by madar juice—14 cases in 1936 as against five cases in 1935. In eight cases the nature of the organic poison could not be determined.

The following cases are selected as of interest:—

Arsenic.—(1) A man had been living as a parasite on his paternal uncle for several years. One morning he went to his uncle's house and had a breakfast of *iddies* (rice cakes) and coffee served by his uncle's concubine. He noticed a peculiar taste in the coffee and asked her about it. The woman told him that it was not coffee but tea and pressed him to drink it all. After drinking the liquid he saw a white deposit at the bottom of the tumbler. He was seized with pain in the stomach and had vomiting and purging. He was removed to hospital where he developed cramps in both legs and suppression of urine, became unconscious and died. Police enquiries disclosed that the woman had purchased *Pashanam* (white arsenic) from a local quack stating that she wanted it for the destruction of rats. We found in the viscera of the deceased arsenic equivalent to about one and two-thirds grains of white arsenic. The remnants of the poison from which the *Pashanam* had been sold were found to be white arsenic weighing about 944 grains. The woman was convicted and sentenced to transportation for life, the lesser penalty being awarded as she had presumably done what she did with the idea that she was releasing her paramour from the clutches of the deceased.

(2) The following is a case of suicide with arsenic. A young man received a telegram that an important relative of his in a high position in life was dead. The young man was admitted to hospital with symptoms of poisoning and there he stated that he had swallowed white arsenic about the size of a hen's egg. He died in hospital. In his stomach contents was found arsenic equivalent to about nine-tenths of a grain of white arsenic. The viscera were not sent to us, probably as it was an obvious case of arsenic poisoning.

(3) A man planned to inherit his brother's property by getting rid of his brother's two sons. He prepared two betel *killies* (Telugu name for packets of areca nuts and lime rolled in betel leaf) and gave one *killie* to each of his nephews. One boy ate it and began to vomit. The other boy passed on the gift to a boy playmate who ate it and began to vomit too. Both the victims were removed to hospital where they recovered after treatment. Arsenic was detected in minute quantities in the vomited matter of each of the victims and in the urine of one of them.

(4) A man went to a village where his wife had been staying, in order to take her home to his own village. At the home of his wife's relations he had a breakfast of cumbu bread and eurd after which he had vomiting, purging and convulsions and died in about fourteen hours. The body was quietly buried by

the wife's relations. A cousin of the deceased grew suspicious and reported the matter to the police, as a result of which the body was exhumed three days after burial. The viscera were sent and they disclosed arsenic equivalent to about two and one-fifth grains of white arsenic. The remnants of the suspected poison seized by the police were found to be white arsenic, weighing about 31 grains. One of the items seized from a shop in a neighbouring town where the purchase had been made was also found to be white arsenic weighing about 2,115 grains.

(5) It is very rarely that the secret seller of poison is detected. A man was found in a collapsed condition on the road-side of a town and was removed by the local scavengers to the hospital. Before the man died he confessed to having eaten, with a suicidal intent, white arsenic purchased from a particular person in the town. The vomit and the viscera showed about two and two-fifths grains of white arsenic. The poison seller's shop was searched by the police and among the several poisons found was a quantity of white arsenic. The seller was convicted for breach of the Poisons Act as he possessed no licence for the sale of poisons and was sentenced to pay a fine of Rs. 100 or in default to undergo rigorous imprisonment for three weeks.

Mercury.—(1) A woman after preparing food fed her children and went to fetch water. After returning home she began to eat but she did not relish the food. She vomited and the vomiting persisted for a long time. She remembered that a boy whom she had seen loitering about the house when she left had vanished by the time she returned. She complained to the police who sent us the remnants of the food for examination. We detected in the food about one grain of corrosive sublimate.

(2) Two persons were given, probably as a practical joke, a confection of jaggery and gingelly seeds by three persons residing in the same village. The victims had vomiting—it is not stated whether they had purging—and recovered. We detected about 21 grains of colomel in the confection and minute quantities of mercury in the vomited matter.

(3) A woman complained before a magistrate that she had been seduced by a man and that, as she was pregnant, her paramour intending to cause abortion tried to force her to swallow three pills. She pushed his hand away and one of the pills dropped to the ground. This pill was picked up and produced in court. About two grains of corrosive sublimate were detected in the pill. As there were no reliable witnesses to substantiate the story of the complainant, the case was dismissed.

Copper.—Of the twelve cases of copper poisoning ten were cases of intended suicide. There were two deaths. In one of the fatal cases was found copper equivalent to about thirty grains of crystalline copper sulphate in the stomach, equivalent to about two-thirds of a grain of crystalline copper sulphate in the intestines and equivalent to about one grain and a half of crystalline copper sulphate in the liver and one kidney. In the other fatal case was found copper equivalent to about one-fourth grain of crystalline copper sulphate in the stomach, equivalent to about two and one-fourth grains of crystalline copper sulphate in the liver, equivalent to about one-fourth grain of crystalline copper sulphate in the kidney, equivalent to about one-fifth grain of crystalline copper sulphate in the intestines and equivalent to about one-fiftieth of a grain of crystalline copper sulphate in the urine.

The following are the details of the non-suicidal cases :—

(1) A sandwich known as *karjikaya* was offered to a young woman to eat. She tasted it and found it bitter. She produced the uneaten portion before the village magistrate and the police sent it in. Copper equivalent to about two grains of crystalline copper sulphate was found in it but no other poison.

(2) A young man, while squatting and urinating according to custom on the side of the street, found in front of him a blue crystalline lump which he thought

was a coloured sweet. He munched it and, finding the taste disagreeable, swallowed it instead of spitting it out. He began to vomit. He called his relations and after telling them what he had done fell unconscious. He was removed to hospital where he recovered after treatment. One of his vomits in the hospital showed copper equivalent to about three-fourths of a grain of crystalline copper sulphate.

Cyanide.—(1) A house was found locked inside with a foul odour emanating from it. The door was opened by the police and two dead bodies were found inside. Cyanide in minute quantities was detected in the viscera of each of them.

(2) A father and son were found dead in a room. There was also a letter written by the father stating that he had administered poison to his son and swallowed poison himself. We found cyanide equivalent to about half a grain of potassium cyanide in the viscera of the son, and cyanide equivalent to about seven-tenths of a grain of potassium cyanide in the viscera of the father.

(3) A man swallowed some powder, walked some distance and fell down unconscious. He vomited twice or thrice and died in hospital two or three hours after swallowing the poison. The viscera and the empty paper in which the poison had been kept were sent for examination. Cyanide in minute quantities in the viscera and also in the washings of the paper was found.

Nitrite.—There were two cases of poisoning, both suicidal, from this poison during this year. Details are given below :—

(1) A young man swallowed 'nitrite of soda' which had been kept for dyeing purposes and died. The post-mortem examination revealed the presence of rigor mortis with discharge of froth from the mouth. The features were calm. The cavities of the heart were empty. The large vessels contained dark and abnormally fluid blood. The lungs were grey and emphysematous. The peritoneum, liver and pancreas were normal. The spleen was slightly enlarged and congested and the kidneys were congested. The mucous membrane of the stomach and intestines was inflamed. The brain and its membranes were congested, and the ventricles were full. The viscera but not the vomited matter were received for examination. Nitrite equivalent to about two-fifths of a grain of sodium nitrite was found.

(2) Some persons were suspected of house-breaking and theft. Two were arrested but the rest absconded. One of these absconding persons was found dead near a pond and a small packet containing a white powder was found by his side. Foam was coming out of his mouth and vomited matter of a green colour was found near the body. The post-mortem examination revealed absence of injuries. The body was decomposed but there were signs of congestion in the lungs, liver and spleen. The kidneys were normal. The peritoneum contained six ounces of dark blood-stained fluid. The mucous membrane of the stomach and intestines showed congestion with bright red patches in places. The bladder contained one ounce of urine. The powder, the viscera and the vomit were sent to us. The powder was found to be potassium nitrite weighing about 620 grains. Nitrite was found in the stomach and its contents equivalent to about four grains of potassium nitrite. The urine showed about 111 parts of potassium nitrite per million parts of uric acid. In the vomit was found about 144 grains of potassium nitrite.

Kerosene oil.—There were two cases of accidental poisoning of children with kerosene oil. In one case a child two years old swallowed some kerosene oil. The child was removed to hospital. At the time of admission the child was unconscious, the reflexes were present, the breathing was rapid with smell of kerosene oil in the breath, and the pulse was fair. The child recovered after the stomach was washed out. In the other case a child three years old drank some kerosene oil and was admitted into hospital conscious, but coughing

badly. The temperature was 97°F., and pulse 140. After the stomach was washed out the child recovered.

Phenol.—(1) A woman swallowed lysol and was removed to hospital, restless and groaning and vomiting frothy material. The pulse was rapid and the temperature sub-normal. She recovered after treatment. Cresols were detected in the stomach wash and in the urine. The amount in the stomach wash was equivalent to about six grains of phenol.

(2) A man drank 'Phenyle' mistaking it for toddy. He died almost immediately. In the viscera were about 21 grains of cresols.

Phenol and aconitine.—A woman probably wanted to make doubly sure of death and swallowed carbolic acid followed by tincture of aconite. She was removed to hospital in an unconscious condition with frothing at the mouth and nose and twitchings of hands and feet. Her stomach was washed out and she recovered. In the stomach wash there was about one and one-fifth grains of phenol and also some aconitine.

Arsenic and aconitine.—A man adopted a boy and settled some property on him, against his wife's wishes. The boy who had been ill for some days died suddenly. The wife was suspected of having poisoned him. The viscera were sent in and in them arsenic was in minute quantities and on examining the viscera further aconitine was found. The general evidence at the trial was so unreliable that the judge acquitted the accused observing that the only facts beyond reasonable doubt were the death of the boy and the detection of arsenic and aconitine in his viscera.

Nux vomica or its alkaloids.—(1) An old woman and her daughter living together found they could not make both ends meet. They resolved to put an end to their lives but to do so in a systematic manner. They went to a tank and made a paste of nux vomica seeds, coconut kernel and jaggery on a stone. After swallowing the paste they bathed in the tank and went home. Both of them developed symptoms of poisoning but the old woman eventually recovered while the daughter died. Strychnine and brucine, the alkaloids of nux vomica, were found in the viscera of the deceased. The police sent two hard particles and also some portion of a fruit. By microscopic and chemical tests the particles were found to be portions of nux vomica seed and the portion of the fruit to consist of the rind, pulp and seeds of nux vomica fruit.

(2) A man who was working in a municipality was suspected of having obtained some of the poison used there for the destruction of dogs and of having mixed it in the food of his victim. The victim ate some of the food and finding it very bitter, suspected poisoning and immediately started walking towards the hospital. On the way, he developed convulsions and died about two hours later without reaching the hospital. Strychnine was present in the viscera, and in the remnants of the food. The rest of the suspected poison was strychnine hydrochloride weighing about 6½ grains.

Datura or mydriatic alkaloid.—Three cases are given below:—

(1) A woman used to visit another woman in the neighbourhood and occasionally used to dine with her. One afternoon the two were dining together. In the middle of the meal the hostess left her meal unfinished and went to the next house to borrow some curry with which to finish the meal. She returned home with the curry and ate the remainder of her meal. She soon felt giddy and became unconscious. Late in the evening she partly regained consciousness and raised an alarm. She was found by the neighbours talking incoherently, very restless and running here and there like a mad woman. The guest of the afternoon had disappeared and so had the jewels of the hostess. A mydriatic alkaloid was found in the vomit of the victim and in the remnants of the food eaten by her. Police investigation revealed that the guest had mixed a preparation of datura seeds in the food of the hostess during her temporary absence.

(2) There were frequent thefts of toddy from the toddy pots attached to the trees in a coconut grove. In order to detect the thief a servant of the lessee of

the coconut grove smeared a paste of datura seeds inside one of the toddy pots on a certain evening. This particular pot was found missing from the tree the next morning. At a *mandapam* near the road a man was found drunk and unconscious with the broken toddy pot close by. The man died without regaining consciousness. A mydriatic alkaloid was found in the viscera of the deceased and in the washing of the broken pot. The servant was convicted and sentenced to pay a fine of Rs. 50 or in default to undergo rigorous imprisonment for one month.

(3) A girl had some mental disorder and a woman introduced a quack to the mother. The terms settled were payment of Rs. 4 for the cost of medicine and a reward of Rs. 10 after the patient was cured. The quack administered medicine for twenty days but the patient was not cured. The mother got her daughter treated by some other man and the second treatment showed some benefit. The quack who first treated the girl now demanded the reward claiming that the cure was really due to the delayed action of the medicine originally administered by him. The mother of the girl refused to pay the reward. The woman who introduced the quack vehemently supported the claim of the quack for the payment of the reward but in vain. The quack powdered some datura seeds, purchased a sweetmeat called *boondi* and mixed the powder with it. He gave the poisoned sweetmeat wrapped in paper to his woman friend and asked her to give it to the patient. She handed the packet to a girl with instructions to convey it to the patient. This girl handed it over to the patient who shared and ate the sweetmeat with her three younger sisters and a younger brother. All five were taken ill and were removed to the dispensary of a local doctor who informed the police. The quack was arrested and in his pocket were found a packet of powder and some seeds. A mydriatic alkaloid was found in the stomach wash of one of the victims and the powder and the seeds seized from the quack were found to be powdered datura seeds and datura seeds. The quack was sentenced to rigorous imprisonment for a period of four years but the woman was acquitted.

Madar juice.—All the fourteen cases of poisoning by madar juice were fatal. In one of these the juice was applied as an abortifacient on cotton swabs which were found, however, pushed into the abdominal cavity. Of the other thirteen cases one was homicidal and the other twelve suicidal. The information as regards symptoms and interval between poisoning and death is very scanty but may be surmised from the following particulars available in some of the cases:—

Case 1.—A woman went out and returned home at noon. She vomited three or four times and collapsed at about half past three in the afternoon. The vomit had the smell of madar juice.

Case 2.—The juice was swallowed at noon, and death occurred at 7 p.m.

Case 3.—The victim vomited in the evening and died at 8 p.m.

Case 4.—The symptoms observed were vomiting, purging, delirium and twitchings.

Case 5.—A woman was well at 11 a.m. She went out to the fields at 3 p.m. and at 5-30 p.m. news reached her son that she was dead in a field a mile from the house.

Summary of post-mortem notes.—Post-mortem notes of thirteen cases of madar juice poisoning have been received; a summary is given.

In three cases the face was bloated. In six cases there was bloody discharge from the mouth and nose. There was congestion of the lungs in eight cases, of liver in six cases, of spleen in four cases, of kidneys in seven cases and of the membranes of the brain in six cases. There was congestion of the inner surface of the stomach in four cases, of the outer surface only in three cases and of part of the inner and the outer surface in one case; the stomach and intestines were normal in the other five cases. Of the eight cases which showed congestion of the stomach, only six showed congestion of the intestines, the intestines in

the remaining two cases being normal. The mode of death was asphyxia with gastro-intestinal irritation in six cases, asphyxia alone without any gastro-intestinal irritation in two cases, gastro-intestinal irritation alone without asphyxia in two cases and syncope without asphyxia or gastro-intestinal irritation in three cases. Four of the cases of asphyxia, one of the cases of gastro-intestinal irritation and one of the cases of syncope showed a co-existent cerebral irritation.

The history of two cases of madar juice poisoning :

(1) A man was beaten with a shoe in the course of a petty quarrel in the presence of his concubine. He took this beating to heart very seriously and said to his concubine 'Life is not worth living after being beaten with a shoe on a festive day (Adi 15th)'. He retired to a room at 5 p.m. and bolted the door. At 6-30 p.m. the concubine and others hearing his groans forced the door open. He died at 9 p.m. The viscera gave the reactions of madar juice.

(2) A woman who had been separated from her husband for several years became pregnant and was delivered of a girl baby. She called two children and giving them a coconut shell asked them to get some madar juice from a plant near by. They did so. She poured some of the juice into the mouth of the infant. About three hours later the infant was found dead. The viscera of the infant and the coconut shell were sent for examination. From the viscera and from the incrustations on the coconut shell the reactions of madar juice were obtained. The woman was sentenced to transportation for life.

Croton seeds.—A man and his brother were suspected of having stolen two bales of yarn and Rs. 200 from their co-tenant. The owner of the property enlisted the services of a travelling mendicant to discover the thief through black magic. When this mendicant wanted to perform certain rites the suspected persons objected on the score that the mendicant had been appraised of their names. This argument appealed to the villagers and the services of the mendicant were dispensed with. At this stage a quack, apparently a specialist in the art of exploiting the gullibility of credulous rustics, entered the arena. On a Friday night he held a *puja* before an idol and told the villagers that, if any of them was responsible for the theft, the wrath of the idol would be visited on the guilty person. This procedure did not produce any obvious reaction on the delinquents. The quack then distributed black pills, one pill to each of the assembled villagers. The two suspected brothers also were each given a pill. These two pills appeared to be white and quite different from the black pills. One of the two brothers protested at what appeared to him to be an obviously invidious distinction but the quack explained that the whiteness of the pills was due to accidental coating with sacred ash. As the explanation was apparently satisfactory this brother gulped down the pill. The other brother who was more cautious ate only a part of the pill and kept the other portion. The first victim who swallowed the whole pill developed purging, vomited blood and died in 20 to 24 hours, the fury of the sacred idol having been apparently let loose on him. The second victim who had swallowed only part of a pill was treated by a doctor and recovered. This doctor, suspecting poisoning, gave information to the police, who secured the uneaten portion of the pill. The viscera of the victim were sent for examination and by microscopic examination, both in the stomach and in the intestines, tissue similar to that found in the outer covering of croton seeds was seen. The police sent the suspected poison and a grinding stone and by microscopic examination of the stone, as well as in the suspected poison, tissue resembling that found in the outer covering of croton seeds was seen. The quack was arrested and sentenced to undergo rigorous imprisonment for two years.

Bamboo shoots.—A woman, who was in criminal intimacy with a man, became pregnant. In order to cause abortion her paramour gave her the juice of crushed tender bamboo shoots to drink. She had vomiting and purging and died in about four hours.

The post-mortem examination revealed discharge of froth from mouth and nose. The heart was full of dark liquid blood and the pericardium contained a quarter of an ounce of serous fluid. The lungs were soft and congested, the section being moist. The throat was congested. The peritoneum was congested. Liver, pancreas, spleen and kidneys were normal. The inner surface of the stomach and intestines was congested and there were spots of hæmorrhage in the mucous membrane of the stomach. The uterus was enlarged and contained a foetus about six weeks old. The membranes of the brain and the outer surface of the brain were congested. Both from the viscera and from the crushed vegetable matter sent, a non-alkaloidal poisonous extract which gave chemical and physiological reactions similar to those given by the non-alkaloidal poisonous extract obtained from tender bamboo shoots was isolated.

Oduvan.—There were two cases of poisoning with oduvan leaves. In each of these two cases with the aid of the microscope, particles of leaf possessing all the characteristic microscopic appearances of oduvan leaf were found.

Oleandar as a love potion.—An old man and his wife were living with their married son and daughter-in-law in the same house. The wife of the old man prepared a chutney of tender tamarind leaves and left it in the house. The daughter-in-law acting on the advice of another woman mixed some substance in the chutney and left it where it was. The son tasted the chutney and rejected it because of its peculiar taste. The wife of the old man thought this was an insult to her skill as a cook and, to show how delicious the chutney was, started to eat the rice and chutney herself. After eating a little she had to give up because of the disagreeable taste. She had vomiting and purging but recovered. The remnants of the chutney were sent for analysis and from them the reactions of oleander were obtained. Further investigation by the police showed that the young woman mixed oleander with the chutney as a love potion to her husband. The case was compounded in court. To all appearances therefore, the potion had worked.

ANALYTICAL NOTES

Bamboo shoots.—The poisonous principle of tender bamboo shoots was extracted in the following manner:—

The acid alcoholic extract, after evaporation of the alcohol, was extracted with water and the aqueous filtrate was treated with lead acetate to remove the tannins. The excess of lead in the filtrate was removed by the addition of sodium phosphate and filtering. The filtrate on extraction with ether yielded a white crystalline residue freely soluble in water. This residue was found to be poisonous to frogs producing strychnine-like convulsions. It had no action when painted directly on the exposed heart of a pithed frog. It does not reduce Fehling's solution. The substance yields with concentrated sulphuric acid a rosy pink colour which on addition of a few specks of manganese dioxide gives a purple colour similar to that given by strychnine but of a lighter tint. Ferric chloride yields with the substance a faint purplish colour destroyed by acetic acid. In a case of suspected poisoning by bamboo shoots we were able to obtain the above reactions from the stomach and its contents.

Madar juice.—This poison has been a subject of study in this laboratory for several years. The botanical name of madar is *Calotropis gigantea*. In Tamil it is known as *erukkam* and in Telugu as *jilledu*. This plant grows wild almost anywhere in South India and is a shrub with thick fleshy leaves and pink or white flowers. On plucking the leaf or incising the stem or leaf, it exudes a thick white milky juice which may be collected in considerable quantities. The juice is used as an abortifacient by local application to the os uteri or is taken by the mouth as a poison.

The juice has a specific gravity of about 1.021 and the total solids amount to about 14.8 per cent (*vide* annual report for 1933). It is acid in reaction. It resembles blood in that after being left for some time

it coagulates to a white coagulum leaving a clear straw-coloured serum. The serum contains about 3 per cent by weight of total solids and about 0.7 per cent of ash. The exact nature of the organic acid or acids in madar juice has not been determined, but the ethyl ester or esters are known to have a distinct characteristic odour. The ester or esters are obtained by making the juice alkaline with KOH, evaporating to dryness, extracting the residue with absolute alcohol and treating the alcoholic solution with dry HCl gas till distinctly acid. On leaving for some time and then diluting with water the characteristic odour of the ester or esters may be recognized.

An alkaline alcoholic extract of the coagulum on extraction with petroleum ether gives a white crystalline extract which can be identified by its colour reactions and also by the fact that it does not yield a digitonide.

The above alkaline alcoholic solution after extraction with petroleum ether, evaporation of the alcohol and treatment with water, or an alkaline aqueous extract of the coagulum after extraction with ether, on acidification with dilute sulphuric acid and further extraction with ether, gives in the ether solution a yellowish brown resin which is nearly insoluble in water but forms a deep yellow solution in aqueous alkali.

The white crystalline extract of madar juice is insoluble in water and was found to be non-poisonous when injected even in oily solutions into animals. The resin when treated with a caustic alkali and neutralized with acetic acid was found to be only slightly poisonous to frogs, about eight milligrams of the resin being necessary to kill a frog about 20 grammes in weight. The serum from madar juice (even after extraction with ether to remove any traces of resin) was found to be poisonous to frogs—.05 millilitre of the serum killing an adult frog in a few minutes. The serum when treated with lead acetate gave a precipitate. The filtrate when treated with hydrogen sulphide and filtered free from lead gave, after driving off the H₂S, evaporating to dryness, extracting the residue with absolute alcohol and evaporation of the alcohol, a poisonous extract half a milligram of which was fatal to frogs, producing convulsions followed by para-

lysis, death and bloating. Two hundred milligrams produced paralysis and death in a rabbit weighing about 34 ounces. The action on the frog and the symptoms and the post-mortem appearances in the rabbit suggest that it probably acts as a cerebro-spinal poison. The extract has no characteristic taste. The poisonous principle of madar juice would appear to be not a resin but a water-soluble principle. The exact nature of this principle is under investigation.

The following scheme of examination is at present in use in this laboratory in suspected cases of madar juice poisoning:—

The alcoholic extract of the viscous or other suspected material is divided into two portions (a) and (b).

Portion (a) is saponified with alcoholic potash and extracted with petroleum ether. The petroleum ether extract is evaporated to dryness, taken up with a little chloroform, treated with a slight excess of a solution of digitonin in rectified spirit, evaporated again to dryness and extracted with ordinary ether. This ether solution on evaporation gives a crystalline residue in the presence of madar juice. A little taken on a depression in a porcelain slab and treated with concentrated sulphuric acid gives a red colour. The addition of a few drops of chloroform and a few drops of acetic anhydride to this red colour changes it to a beautiful purple. The test may also be carried out on a watch glass placed over a porcelain slab.

The alkaline alcoholic solution after extraction with petroleum ether as above is evaporated nearly to dryness, taken up with absolute alcohol and filtered. The filtrate on treatment with dry HCl gas in excess and keeping for some time shows on dilution with warm water a characteristic pleasant ester odour in the presence of madar juice.

The other portion (b) is evaporated to dryness, taken up with water acidulated with acetic acid, filtered, treated with excess of lead acetate and again filtered. The filtrate is treated with excess of H₂S, filtered free from lead and evaporated to dryness over a water-bath. The residue is extracted with absolute alcohol and the alcoholic solution evaporated to dryness. A little of this extract on injection into a frog produces, in the presence of madar juice, convulsions ending in paralysis, death and bloating.

Correspondence

MEDICAL PRACTICE IN BENGAL

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—In the August 1937 number of the *Indian Medical Gazette* we have read an article written by Lieut.-Colonel Phipson, on the economic outlook of medical practice in India, in which he has described the very bad economic condition of the medical practitioners by facts and figures.

* * * *

The *bona fide* scientific medical treatment is costly no doubt and the majority of the villagers cannot afford to have it, and that is why qualified medical men come back unsuccessful from village careers in so large numbers and so frequently, and declare that medical practice in a village by a qualified medical man is impossible. For this reason, so many medical graduates and licentiates huddle together in towns and refuse to go to villages where innumerable people are dying at the hands of quacks in a pathetic manner, and this is no doubt a disgrace for a nation which claims to be civilized. Those who are in controlling positions in the Government are so apathetic that it seems as if they are quite unaware of the gravity of the situation. The attention of the persons in power should be drawn to this state of affairs and the following measures should be adopted with due earnestness without further loss of time.

- (1) Abolition of quack practice by legislation,
- (2) state subsidy system in rural areas, (3) health

insurance scheme in urban areas, and (4) appointment of licentiates as sanitary officers in health units.

In conclusion, it may be added that production from medical colleges and schools should be restrained, and adjusted according to the demand and supply rules, and production in excess of the needs of the country should be considered as a disastrous procedure in the long run.

Yours, etc.,

H. CH. BHATTACHARYA, M.B.

SERAMPORE,
DISTRICT HOOGHLY,

MAULED BY A LEOPARD

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—I would like to report a case of leopard mauling because two comparatively new drugs were used in the case.

A man was admitted on 26th February, 1938, having been mauled by a leopard that afternoon. He had 3 parallel claw cuts across the scalp each about 4 inches long and down to the bone. He was operated on 5½ hours after the accident by the chief medical officer, Dr. H. Flaek, to whom I am indebted for permission to publish this. The wounds were very carefully cleaned with Dettol and the edges cleanly excised right down to the bone, and sutured.

Soluseptasine and Proseptasine (May and Baker) were given—5 c.cm. of Soluseptasine were given that night, and for the next two days 5 c.cm. were injected night and morning and 6 tablets daily of Proseptasine for 5 days. The temperature rose to 101°F., the highest, on the 28th morning and was completely down to normal on 3rd March. The wounds healed, the stitches were removed on the 4th, and one small sinus which remained was completely healed in two weeks.

Yours, etc.,
B. L. SEN, L.M.F.

CASHEW FRUIT AND VITAMIN C

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—Let me bring to your kind notice the following fact about cashew fruit (not the nut):—

Cashew tree grows wildly on the west coast and the yield is very abundant from February till May in South Kanara. We know something about the nut and its kernel, but very little about the fruit.

Cashew fruit is very juicy and its taste is not bad. It is extremely cheap—a dozen fruits cost a quarter anna and sometimes less. It is highly recommended in South Kanara in smallpox (when the epidemic falls during the yield), and also for mothers to improve the quality of breast milk.

I happened to make rough experiments with the cashew (fruit) juice with regard to its vitamin-C content; the figure obtained was high and on comparing it with that of orange juice, I found cashew juice to be 6 to 8 times stronger in vitamin-C content. I corresponded with the Director of the Nutrition Research Laboratories, Dr. W. R. Aykroyd of Coonoor, to whom I sent two parcels of cashew fruits and he was very kind to send me his result in the following reply:—

'The vitamin-C content of the sample of cashew fruits sent by you has been determined; the figure obtained being about 376 mg. per 100 c.cm. of juice. This is a high figure as compared with that given by the majority of fruits.'

Knowing the above fact and also the common belief in South Kanara as regards the beneficial effect of the fruit in smallpox, I want to know whether there is any close dependence of smallpox on vitamin-C deficiency. No doubt an adequate supply of vitamin C plays an important part in the dietetic treatment of all fevers. But in smallpox, its epidemic constitution, the hæmorrhagic variety, its severity during pregnancy and in the old—all these may depend upon the deficiency of vitamin C—seasonal as well as individual, if the common belief can be relied upon.

Yours, etc.,
K. M. SHENAI, L.M. & S.

MANGALORE,
18th March, 1938.

THE DRUG CONTROL BILL

To the Editor, THE INDIAN MEDICAL GAZETTE

SIR,—Towards the latter part of 1937 a bill was introduced in the Legislative Assembly of the Government of India to regulate the import into British India of certain drugs and medicines.

The bill has been referred to a select committee which is expected to meet towards the end of this month.

The necessity for legislation to ensure pure and potent drugs (whether imported or manufactured in

India) in the market has been keenly felt. But the present bill is only a half-hearted measure inasmuch as the drugs manufactured in India are not included within its orbit.

The main cause of circulation in the market of adulterated or understrength drugs is the popular demand for cheapness and the tendency of unscrupulous manufacturers and dealers to exploit this is the reason why proper comprehensive legislation is a necessity and this fact was recognized by the Drugs Enquiry Committee presided over by Colonel Chopra in 1930-31.

If legislative control is introduced only to regulate imports of drugs and medicines the object will not be served. Such a course would only help to put the manufacturers of genuine drugs in India to a positive disadvantage. The stamp of genuineness, so to say, under which the imported drugs only will be sold will serve as a discrimination against genuine drugs manufactured in India and the drug industry in India itself will be put under a stamp of inferiority. Therefore, we suggest that with the control of imported drugs, simultaneously there should be introduced control of drugs manufactured in India.

Our past experience in the matter of excise policies of the different provincial governments teaches us that if such control is not exercised from the central government then there are bound to be different working rules in different provinces which will check free flow of trade in drugs. The Government of India felt this difficulty in the autonomous excise policies of the provincial governments, and recently had to call in a conference of excise commissioners to find out ways and means of making the provincial governments fall in one uniform line. Lest this error be repeated in the present matter of control of drugs we suggest that the control of drugs (whether imported or manufactured in India) should be by the central government.

Further, if the present bill and other future legislation on the same lines are to function, the government in framing the rules thereunder should be aided by expert opinion of non-officials, and it was in these circumstances that the Drugs Enquiry Committee also recommended formation of an advisory board.

Then there are various independent states in India from which manufactured drugs filter inside British India. The government should take steps that these states also pass similar legislation.

Finally as the testing laboratories for the purpose of the working of the Legislative measure will have necessarily to be under the control of the government it is desirable in order to ensure public confidence that government shall not be connected directly or indirectly with the manufacture of drugs.

To sum up, our suggestions are:—

1. The control of imported drugs and drugs manufactured in India should be simultaneous and be exercised by the central government.
2. There should be a provision for a statutory advisory board in the enactments.
3. Steps should be taken that independent states in India do also pass enactments exercising similar control within their area.
4. Government should not directly or indirectly be competitors with indigenous manufacture of drugs.

We have submitted a memorandum to the above effect to the Law Member, Government of India, and several public bodies have also expressed similar views.

Thanking you,

Yours, etc.,
J. N. LAHIRI,
Manager.

BENGAL CHEMICAL & PHARMACEUTICAL
WORKS, LIMITED,
164, MANIKTALA MAIN ROAD,
CALCUTTA,
24th March, 1938.

Service Notes

APPOINTMENTS AND TRANSFERS

Lieutenant-Colonel B. F. EMINSON, Civil Surgeon, Hyderabad, is appointed temporarily as the Director of Health and Prison Services, Sind, Karachi, *vice* Lieutenant-Colonel N. Briggs.

Lieutenant-Colonel W. J. Webster, M.C., is appointed to officiate as Director, Central Research Institute, Kasauli, *vice* Colonel J. Taylor granted leave, with effect from 1st April, 1938.

Lieutenant-Colonel G. C. Maitra, on return from leave, assumed charge of the duties of the Director, Pasteur Institute of Burma, Rangoon, on the forenoon of the 7th March, 1938.

Major J. Carrey joined the Indian Military Hospital, Rawalpindi, on reversion to Military duty from civil employment, Central Provinces, on 4th March, 1938.

Major R. W. H. Miller to be Officiating D. A. D. M. S., Southern Command. Dated the 5th March, 1938.

Major W. T. Taylor is appointed as Officer in charge, Medical Store Depot, Bombay, with effect from the 7th March, 1938.

Major J. F. Shepherd, on return from leave, to act as District Medical Officer, North Arcot, and Superintendent, Government Headquarters Hospital, Vellore, with effect from the date of taking charge.

Captain G. F. Harris was transferred to civil employ as Medical Officer, Tochi Scouts, on 26th February, 1938.

Subject to the approval of the Secretary of State for India to the transfer of Captain M. H. Shah to the Civil Branch of the Indian Medical Service, that officer is appointed on probation as Additional Civil Surgeon, Delhi, with effect from the 1st March, 1938.

Captain B. A. Porritt on reserve duty in the Government General Hospital, Madras, to act as the District Medical Officer, Tanjore, Superintendent, Rajah Mirasdar District Headquarters Hospital, and Medical Officer, Borstal School, Tanjore, with effect from the date of taking charge.

LEAVE

Colonel J. Taylor, C.I.E., D.S.O., is granted combined leave for 4 months, with effect from the 1st April, 1938.

Lieutenant-Colonel R. Sweet, D.S.O., Officer in charge, Medical Store Depot, Bombay, is granted 6 months' combined leave *ex-India*, with effect from the 5th February, 1938, the first two months being privilege leave and the rest on medical certificate.

In modification of previous order Lieutenant-Colonel P. Verdon, Acting Superintendent, Government Ophthalmic Hospital, and Professor of Ophthalmology, Medical College, Madras, is granted leave, *ex-India*, for 2 months and 15 days on average pay, and 6 months and 15 days on half-average pay, with effect from the 8th February, 1938.

Lieutenant-Colonel N. Briggs, Director of Health and Prison Services, Sind, is granted leave *ex-India* for 8 months, with effect from the 10th March, 1938.

Lieutenant-Colonel J. S. S. Martin, Officer Commanding, Combined Indian Military Hospital, Kohat, proceeded on 8 months' combined leave *ex-India*, with effect from the 11th March, 1938.

Lieutenant-Colonel M. D. Wadia, Civil Surgeon, Ambala, proceeded on leave on average pay for 3 months and 19 days, with effect from the 16th March, 1938, preparatory to retirement from the service.

Lieutenant-Colonel A. C. Macrae, Officer Commanding, Combined Indian Military Hospital, Dehra Dun, proceeded on 3 months' combined leave *ex-India*, with effect from the 25th March, 1938.

Lieutenant-Colonel E. W. O'G. Kirwan, Professor of Ophthalmic Surgery, Medical College, Calcutta, is granted leave for 3 months, with effect from the 18th March, 1938, or from any subsequent date on which he is relieved.

Lieutenant-Colonel H. S. Cormack is granted 8 months' leave on average pay from the afternoon of the 24th March, 1938.

Lieutenant-Colonel J. H. Smith is granted an extension of leave for 6 months to the 26th September, 1938.

Major C. F. J. Cropper is granted 10 months and 29 days' leave, including leave on average pay for 4 months and 5 days, leave on half-average pay for 24 days and study leave for 6 months. He is also permitted to combine with his leave the College vacations from the 22nd March, 1938, to the 15th June, 1938, and from the 1st October, 1938, to the 31st October, 1938, both days inclusive.

Major T. A. Malone, Staff Captain (Medical), Rawalpindi District, proceeded on 12 months' combined leave *ex-India*, with effect from the 14th March, 1938.

Major G. J. Joyce, who was on leave *ex-India* on average pay till the 20th March, 1938, has been granted, by the High Commissioner for India, an extension of his leave by 2 months up to the 20th May, 1938.

Major H. J. Rice, C.I.E., D. A. D. M. S., Southern Command, proceeded on 3 months' combined leave *ex-India*, with effect from the 5th March, 1938.

Major K. S. Fitch, Civil Surgeon, Hooghly, is granted leave on average pay for 8 months and in continuation leave on half-average pay for 2 months, with effect from the 10th November, 1937.

Previous notification is hereby cancelled.

Captain C. F. Garfit, who was doing general duty at the Mayo Hospital, Lahore, has been posted as Civil Surgeon, Jelum, *vice* Captain B. Temple-Raston, transferred to Murree.

Captain R. C. Draup, Officer in charge, Brigade Laboratory, Bannu, proceeded on 6 months' combined leave *ex-India*, with effect from the 11th March, 1938.

Captain D. W. Taylor, Ophthalmic Specialist, Lucknow, proceeded on 7 months and 7 days' combined leave *ex-India*, with effect from the 13th March, 1938.

PROMOTION

Promotion to present rank of Major B. D. Khurana is antedated to 28th April, 1937.

Captains to be Majors

J. S. McMillan. Dated 12th September, 1937.

M. R. Sinclair. Dated 1st February, 1938.

C. F. J. Cropper. Dated 8th February, 1938.

Lieutenants (on probation) to be Captains (on probation)

W. A. Hopkins. Dated 8th January, 1938, with seniority from 31st August, 1937.

J. L. Mewton. Dated 9th January, 1938, with seniority from 1st March, 1937.

J. W. R. Sarkies. Dated 9th January, 1938, with seniority from 31st August, 1937.

L. U. Kamm. Dated 9th January, 1938, with seniority from 31st August, 1937.

T. Denness. Dated 10th January, 1938, with seniority from 31st August, 1937.

The seniority of Lieutenant (on probation) A. E. B. de Courcy Wheeler in that rank is antedated to the 1st January, 1937.

RETIREMENTS

Lieutenant-Colonel T. D. Murison. Dated 7th November, 1937.

Lieutenant-Colonel Som Dutt. Dated 28th March, 1938.

RELINQUISHMENT

Captain S. S. Alam (Temporary Commission). Dated 9th November, 1937.

Notes

'WELLCOME' BRAND CALCIUM MANDELATE COMPOUND

THE introduction of 'Wellcome' brand calcium mandelate compound by Burroughs Wellcome and Company represents an important advance in mandelic acid therapy for urinary infections. Calcium mandelate has been found to be as effective therapeutically as sodium or ammonium mandelate and, since it is free from many of the disadvantages associated with these salts, may be regarded as the preparation of choice. In the stomach calcium mandelate is broken down into calcium chloride, most of which is converted into non-absorbable calcium salts in the intestine, and mandelic acid which is excreted unchanged in the urine in sufficient concentration to produce a bacteriostatic effect. In the degree of urine acidity produced it is equal to ammonium mandelate and superior to sodium mandelate.

'Wellcome' brand calcium mandelate compound is a suitably flavoured powder of which 4.4 grammes (the normal adult dose) is equivalent to 3 grammes of mandelic acid. It is entirely free from the disagreeable taste characteristic of sodium and ammonium mandelates and readily mixes with water to form a suspension. The product is issued in bottles of 125 grammes, together with a measure corresponding to an adequate dose, and a supply of test papers to enable the urine acidity to be checked daily during administration.

FUMIGATION WITH CALCID

FUMIGATION of rats with calcium cyanide is practised on a fairly wide scale in India. It is a method of treatment that is rapidly superseding other measures such as trapping and poison baiting as it is easily applied and the gas evolved from the calcium cyanide is one of the most deadly known. The method is simple in that it is only required to blow a very small quantity of the material into a rat burrow, close the burrow up and leave it—no rat or flea will remain alive in it. Considering the labour involved and the range of efficiency of the gas it would be difficult to find a more economical method.

The lethal property of hydrogen cyanide is well known to most people and because of the danger to human life it has not, until very recently, been used as a fumigant to the extent that it might have been. It is however available in various forms which greatly simplify its application, and with ordinary care, these can be handled with hardly any danger at all to human beings.

It is not sufficient, however, to be well manned and well equipped, but the greatest factor governing successful results lies in the organization of a campaign. Rats by nature are venturesome creatures and forage far afield, and unless realization of this fact is constantly borne in mind any scheme for exterminating them, no matter what the medium employed, can hardly be expected to prove entirely successful. Haphazard methods of attack are uneconomical, and, from a plague preventive point of view, in an endemic area, useless.

A booklet has been issued by the Haver Trading Company which is devoted almost entirely to the practical application of Calcid (a high grade calcium cyanide) as a rat and flea control measure, and, in order that it can serve as a useful guide to health officers, an endeavour has been made to make the practical side as complete as possible and to cover the varied conditions encountered in field work.

Primarily it is intended to bring to the notice of health officers concerned in plague prevention work the value of an exterminating medium which, if used systematically, will bring them nearer to the solution of their

big problem—entire eradication of plague-susceptible rodents.

The properties of Calcid are described and sound practical advice given for handling it to the best advantage, so that the intending user need have no fear that he will have to experiment with an untried article, or, as a novice, commit some detrimental action through nervous uncertainty.

We have mentioned that the use of hydrogen cyanide in public health work has been handicapped owing to its dangerous properties, but the reader should know that the calcium cyanides (which give off hydrogen cyanide) are used very extensively as citrus tree fumigants in nearly every country in which citrus is grown. Literally hundreds of tons are used annually for this purpose and although no gas-masks are worn by the fumigators, and in spite of the fact that relatively large quantities of the gas are released, death as a result of accidental poisoning is unknown.

When employing calcium cyanide for rat and flea destruction purposes the quantities of gas used are generally very much less than those used for tree fumigation, but certain precautionary measures must be taken because other factors are not the same. In one instance there is an open orchard—in the other a populated area, and though the possibility of any one succumbing to gas-poisoning during ordinary 'preventive' measures is remote, the health authority cannot afford to take the slightest risk.

The booklet has been written in the simplest language, without any attempt at literary style or grammatical perfection. Subordinates who are responsible for applying the material will be able to follow the text without difficulty and so take some part of the responsibility from the shoulders of the senior medical or plague officer.

Publishers' Notice.

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles are entitled to receive 25 reprints *gratis*; additional reprints can be obtained on payment. No reprints will be supplied unless contributors ask for them at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions and Advertisements should be addressed to THE PUBLISHERS, *The Indian Medical Gazette*, P. O. Box No. 54, Calcutta.

Annual Subscription to 'The Indian Medical Gazette', Rs. 16 including postage, in India. Rs. 19-8 including postage, abroad. Single copies Re. 1-8 each. Back numbers (if available) for the previous year Rs. 2-8 each, and all other back numbers Rs. 5 each.

Subscribers who so desire may have their copies packed flat in a strong envelope. The extra charge per annum is Re. 1-8 which should be added to the subscription. The envelopes are strongly made, and the *Gazette* is not folded, nor creased, in transit.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication. When any such article appears in the *Indian Medical Gazette*, the copyright automatically becomes the joint property of the author or authors, and of the publishers.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

TREATMENT OF SCHIZOPHRENIA BY INDUCING EPILEPTIFORM SHOCKS BY THE DRUG CARDIAZOL

AN EXPERIMENTAL STUDY OF 42 CASES

By J. E. DHUNJIBHOY

LIEUTENANT-COLONEL, I.M.S.

Medical Superintendent, Ranchi Indian Mental Hospital (Bihar)

SCHIZOPHRENIA is the psychiatrist's biggest and most urgent problem, and constitutes a challenge to investigators in every field of medical research. Its ætiology is unsettled, its pathology unknown and its clinical limits in dispute, and yet it is a more serious problem than either tuberculosis or carcinoma. In the United States of America statistics show that each year some thirty to forty thousand individuals soon after adolescence or in the first flush of manhood or womanhood fall victims to this dread disease. Annually at least more than one-quarter of the patients admitted to mental hospitals in Europe and America are suffering from this disorder and the number of cases admitted to mental hospitals in India would appear to be similar. It takes its toll of the young at an age when the promise of life is normally at its brightest and strikes at the poor and rich alike. It cuts off its victims from the normal human activity and intercourse, and condemns them to a life hemmed in by high walls and prohibitions which no matter how camouflaged by kindness or softened by sympathy make mere existence a living death or what the present-day psychiatrists prefer to call 'a vegetative existence'. The importance of schizophrenia from the mental hygiene (public health) viewpoint needs no further emphasis and preventive measures are of the utmost importance. In the early stages the prognosis is not always poor and the condition does not always end in dementia. Spontaneous remissions are also possible, especially in the early stages of the illness but many of these remissions are temporary and of comparatively short duration. The percentage and duration of spontaneous remissions are extremely arbitrary. Some authorities put down the figure for spontaneous remissions to be between 10 to 15 per cent. The numerous theories often advanced to explain schizophrenia are hopeful confessions of our ignorance; it is only natural that its treatment should be empirical. As the line of treatment is empirical, a large variety of organic and inorganic substances have been tried by psychiatrists from time to time and they are still applying these methods in order to ameliorate the condition of the patients rather than stand by and watch them deteriorate, and their efforts are sometimes

rewarded by success. Among the various methods of empirical treatment of schizophrenia the following hold pride of place :—

(1) Pyrexial treatment. The production of fever in patients by injections of typhoid vaccine, sterile milk, pyrifur sulfosin, Dmelcos vaccine, by inoculation of malaria, by diathermy or by any other means.

(2) Glandular products of various kinds, especially testicular, thyroid and ovarian extracts.

(3) Prolonged narcosis by various sedative drugs such as somnifaine, soneryl, sodium amytol, nembutol, luminal, somnos, hypnol, and sodium evipan.

Prolonged narcosis by somnifaine is still in vogue in England and on the Continent.

Advocates of one or more of the above-stated empirical methods of treatment of schizophrenia will not be found wanting, and no doubt these methods have achieved sporadic success and have caused a certain amelioration of symptoms, yet the results have not been such as to commend them universally for the routine treatment of schizophrenia. Moreover all the above methods of empirical treatment of schizophrenia were tried by me from time to time on the schizophrenics of the Ranchi Indian Mental Hospital, which is the largest and one of the most modern mental hospitals in India. The results of our successes and failures with these methods of treatment were fully stated in our annual reports of the hospital, and some with encouraging results were published in medical journals. Recently to the vast armamentarium of the schizophrenic empirical treatment are added the insulin hypoglycæmic therapy by Dr. Manfred Sakel of Vienna and the epileptiform shock therapy by the drug cardiazol by Dr. Ladislaus V. Meduna of Budapest. It is the writer's aim in this paper to describe in full his own experience of 'convulsive therapy' of schizophrenia as evolved by Dr. Meduna.

Since the introduction of 'insulin therapy' in schizophrenia by Dr. Manfred Sakel typical epileptiform attacks are frequently observed in patients undergoing this treatment. Both in Vienna and Munsingen (Switzerland) cases have been observed with such attacks during insulin treatment and it was reported that when an epileptiform attack appeared it produced a very favourable effect. Recently a case of status epilepticus during insulin treatment was recorded by Gillies (1937). Incidentally Dr. Hunter Gillies in this article has also mentioned the work of Dr. Ladislaus V. Meduna. When I was in Budapest in 1935 I was invited by my friend and colleague Dr. Meduna to see his treatment of schizophrenia at the Royal Hungarian State Mental Hospital, Budapest. I was so impressed with all that I saw and more so with the good results obtained by Dr. Meduna by this treatment that I decided to try the treatment in my hospital on my return to India. I will describe in short the

theory and technique of Dr. Meduna's treatment by cardiazol before I narrate my own experience with this treatment.

The theory.—Dr. Meduna for a long time held a theory that there might be some biological antagonist to schizophrenia just as Hofrat Professor Wagner-Jauregg found biological antagonism between malaria and neuro-syphilis. Dr. Meduna with this end in view made an exhaustive study of the literature on epilepsy and schizophrenia and accidentally he came across an article written by one of the Continental authorities on epilepsy wherein the author had stated that epilepsy and schizophrenia are very seldom found in combination in one and the same person. Dr. Meduna was very much impressed with this new knowledge and he made further studies on this line and was later convinced that there was some biological antagonism between schizophrenia and epilepsy. For years he carried out experiments, firstly on animals and later on patients, with various drugs to induce epileptiform fits and found that 25 per cent camphorated oil solution given intramuscularly produced the best results. He obtained 10 remissions out of the first 26 cases of schizophrenia treated by camphor injections, but later he found that the tolerance to camphor with patients differed greatly and he was compelled to seek a more stable and reliable medicament for this purpose. Finally, he tried Knoll's cardiazol and the results obtained were highly satisfactory. Cardiazol (penta-methylene-tetrazol) is generally known to the profession as a water-soluble synthetic preparation having pharmacological effects similar to camphor, to which it is distantly related to camphor chemically. The dose given for inducing epileptiform fits is far in excess of the one usually prescribed in clinical practice of this useful drug, yet it has no injurious effect on the normal heart and is not cumulative in its action. I have no intention in this article of entering into any discussion about the theory on which this treatment was evolved by Dr. Meduna, however fantastic it may appear. I am only dealing with the practical side of it, viz, the results obtained by this treatment. Dr. Meduna claims to have obtained 40 to 50 per cent remissions in schizophrenics by this treatment.

Technique and dosage as evolved by Dr. Meduna.—Dr. Meduna starts the treatment by using a 10 per cent solution of cardiazol, commencing with an injection of 5 c.cm. and increasing each injection by one c.cm. until the fit is produced. Should 5 c.cm. induce a fit the dose for that particular patient is not increased. One may use a solution of greater strength but in any case Dr. Meduna suggests commencing with 0.5 gramme of cardiazol and if necessary increasing each successive dose by 0.1 gm. The intravenous route is always preferred but if this is not possible on account of the depth of the veins the injections may be given intramuscularly the dose then being increased from

0.3 gm. to 0.5 gm. above the intravenous dose. No definite plan can be laid down as to how many injections are necessary for each case as they vary considerably in different patients. Some schizophrenics have shown full remissions with 3 or 4 injections and others have not improved at all after 20 to 30 injections. However, Dr. Meduna suggests that no case should be given up as hopeless for this treatment without giving the patient the benefit of at least 20 such injections, or, to be more accurate, 20 such convulsive shocks. Dr. Meduna has tried this treatment on a large number of cases and has obtained 40 to 50 per cent remissions without any untoward results.

Contra-indications for treatment.—The treatment is contra-indicated in acute bodily illness or chronic disease affecting the heart, blood vessels, lungs and kidneys.

Our experience with cardiazol therapy

For the purpose of this experiment I selected 42 typical cases of schizophrenia. Cardiazol was not obtainable in India in powder form so I wrote to Messrs. A. G. Knoll for a free supply of this powder and the firm readily responded to my request and sent me a sufficient quantity for the experiment. The majority of cases selected were chronic schizophrenics who had not responded to any of the known treatments for this disease.

Preparation of patients for cardiazol treatment

A routine examination of heart, urine and blood pressure of each patient was made a day previous to the one fixed for injection. All patients are given a cup of hot milk at about 7 a.m. and are then taken to a special ward opened for the purpose, where the beds are screened from each other. The injections are given as a rule at 9 a.m. An attendant is posted with a tampon in his hand behind the head of the patient's bed. One attendant is placed on either side of the patient's bed to prevent him from falling out or being injured during the fit. The fourth attendant prepares the patient's arm and holds it to be ready for the intravenous injection by the doctor. A second doctor stands at the foot of the bed with a watch to time the injection and the fit and to make clinical observations. In order to allow unhampered movements of the extremities during the fit no clothes are allowed except short pyjamas which are also undone at the waist. The cardiazol is then injected, due attention being paid to the speed at which the solution enters the vein.

A typical fit.—Immediately after the injection and sometimes before the needle is withdrawn the patient's eyelids begin to quiver—a sign found in the majority of patients—the face becomes anæmic, the body stiffens and the patient makes a few futile attempts to get away from the bed by irregular movements of the hands and feet. He then loses consciousness

and a typical tonic stage sets in. The posture is with clenched hands, wrists and elbows slightly flexed, arms held to the sides, the legs extended, also the back, and the face becomes cyanosed. The patient at this stage never fails to open his mouth and he keeps it conveniently open for a few seconds and this is the time the attendant inserts an improvised tampon to prevent the patient from biting his tongue. The tampon is made 6 inches long and $\frac{1}{4}$ inch thick. In the few seconds that follow the clonic stage starts and the convulsions take the form of irregular jerks and spasms. During this phase some patients pass urine and some ejaculate with or without erection. At the end of the clonic stage the patient goes into a deep coma-like sleep which lasts from 5 to 20 minutes. The patient then regains consciousness; he first appears to be confused and dazed and it is better to let him sleep and not to disturb him with questions. I always encourage the patients to sleep for a few hours and no one is allowed to leave the bed for at least 5 to 6 hours after the fit. As far as possible no food or drink should be allowed for a few hours after the injections as they are often rejected by the stomach if given earlier. Our routine is to give injections at 9 a.m. and to serve food at about 2 p.m. Formerly the injections were given twice a week but now they are given every alternate day.

Collective and individual peculiarities in our cases

(1) The tonic and clonic stages differed in individual cases. Some had a good tonic stage and others clonic. We found that those patients who had good and prolonged clonic stages eventually derived much benefit by the treatment.

(2) Fifteen patients invariably showed post-epileptic excitement which lasted for a few hours after each injection, but in the night they slept well without any hypnotics.

(3) Four patients after the fit always used to scratch their necks, thighs, groins and arms for a few minutes only.

(4) Two patients always used to spit after coming out of the fit and this mannerism continued for a few minutes.

(5) Five patients always gave an 'epileptic cry' before the onset of the tonic stage.

(6) Two patients always smacked their lips for a few minutes after coming out of the fit, as if they had some taste left in the mouth by the drug and their gestures proved that it was by no means pleasant.

(7) Ten patients always remained in an hilarious condition after the fit for about half an hour. They sang songs and showed feelings of well-being almost like the first stage of alcohol intoxication.

(8) One katatonic patient who had murdered his brother and never admitted it before the

court or to anybody else suddenly one day after the fit made a frank confession of his crime and described in detail the scene of murder which when verified with the police report was found to be correct. On the other hand we tried to get a confession out of another patient who was also charged with murder and would not admit it, but we failed in this case.

(9) A katatonic with marked *flexibilitas cerea* and mutism on the day of the fifth injection implored us not to give him the treatment and said that he would act and behave like a normal person in every way. I gave him a chance and he behaved very like a normal person for two days but relapsed on the third and the treatment was continued in his case and after a full course he showed a great improvement in his katatonic condition.

(10) Three patients during the course of injections twice showed conditions like larval epilepsy or epileptic equivalents, i.e., their fits after a full dose of cardiazol (1 gm. in 10 per cent solution) were replaced by a condition of excitement almost amounting to furor which lasted for 15 to 30 minutes. On coming round the patients had no memory of their excitement and they showed complete amnesia of events, a point of great medico-legal importance.

(11) Some patients as soon as the drug was injected started coughing a little as if the drug had irritated their throats and they invariably went into fits. The cough is now regarded by us as an unfailing sign for the production of fits.

Dangers and complications.—I am glad to be able to state here that not a single case showed any dangerous symptom and I agree with the findings of Dr. Meduna that the treatment is perfectly free from any danger in selected cases. Four patients during fits had dislocations of shoulders which were soon put right when they were in the amnesic state and with proper care the trouble never recurred, although we subsequently induced many fits in the same patients.

It is said that any hypnotic, especially morphia, hyoscine, paraldehyde and sodium evipan, will counteract any dangerous symptoms produced by cardiazol. In our emergency tray these drugs were always kept ready for immediate use but we never had any occasion to use them.

Comments

We found in our series of cases that those patients in whom severe fits were induced by the initial dose of 0.5 gm. of cardiazol for the first 8 to 10 injections showed better improvement than those in whose case the initial dose had to be increased in the first 4 or 5 injections to 1 gm.

(2) Rapidity of injections also plays a great part in the induction of fits. We experimented

with large doses of stronger solution and injected the dose very slowly and no fits were produced but in the same patients the next day we gave 0.5 gm. dose at a speed of 1 c.cm. per quarter second and produced beautiful fits. Our usual rate of injection is 5 seconds.

(3) The treatment is very simple and can be undertaken by any physician with a little knowledge of the technique.

(4) It is true that the induction of epileptiform fits in patients is not a very pleasant sight for onlookers but to the patients themselves it makes no difference as they become unconscious at the very onset of the fit and even on recovery they do not remember anything. In fact, they have complete amnesia of events. Patients generally learn about the fits from other patients or the attendant staff, or at times after recovery from a fit they sometimes try to peep through the screen when other patients are being given the same treatment in their ward, although every effort is made to prevent the patients from getting the information.

This point was further elucidated by giving injections to one of the staff who volunteered to undergo this treatment in the cause of science. He also informed us that he had no knowledge of what happened from the time the needle was introduced into his vein until he recovered his senses. He further said that he suffered no pain or felt no shocks and did not remember anything (complete amnesia of events).

(5) On the days when no cardiazol is given, patients are allowed to attend the occupational therapy classes and to take part in all daily activities of the hospital life.

Results of our experiment and conclusions

Out of 42 cases selected for the experiment there were 31 males and 11 females. The following table shows the number and types of schizophrenies selected and their sex :—

TABLE I

Number of cases	Types of schizophrenics	Male	Female	Total
15	Katatonic ..	11	4	15
17	Hebephrenic ..	13	4	17
8	Dementia paranoides.	6	2	8
2	Simple dementia	1	1	2

Table II shows the results of our experiment on 42 cases :—

TABLE II

Number of cases	Types of schizophrenics	Full remissions	Improved	Stationary
15	Katatonic ..	7	4	4
17	Hebephrenic ..	5	9	3
8	Dementia paranoides.	1	2	5
2	Simple dementia	2

Table III gives more information of the 13 cases who got full remissions and were subsequently discharged as quite recovered by the board of visitors of the hospital :—

TABLE III

Serial number	Types of schizophrenics	Sex	Period of stay in the hospital before the commencement of the treatment			Number of injections given and amount				REMARKS
			Y.	M.	D.	Total	0.5 g.	0.6 g. to 0.8 g.	1.0 g.	
1	Katatonic ..	M.	3	5	..	20	7	..	13	Discharged as fully recovered.
2	Hebephrenic ..	M.	..	11	10	11	11	He has now rejoined his office as a clerk.
3	Dementia paranoides	M.	1	13	8	..	5	Discharged as fully recovered.
4	Katatonic ..	M.	1	1	..	20	7	2	11	Do.
5	Do. ..	M.	..	6	6	11	8	3	..	Do.
6	Do. ..	M.	..	3	8	10	4	4	2	He has now rejoined his service on the railway.
7	Do. ..	M.	..	3	3	7	1	..	6	He is now working as a salesman.
8	Hebephrenic ..	M.	1	6	..	6	4	2	..	Discharged as fully recovered.
9	Katatonic ..	M.	..	3	15	5	5	Do.
10	Hebephrenic ..	M.	..	2	18	11	8	3	..	Do.
11	Katatonic ..	M.	..	5	8	30	27	3	..	Do.
12	Hebephrenic ..	F.	..	3	19	12	12	Do.
13	Do. ..	F.	..	11	0	11	3	8	..	Do.

Table III shows that schizophrenics are curable in their early stages and the earlier the treatment is applied the better are the results. The majority of the cases who improved under treatment were early cases as shown in column 4 of table III. All the discharged patients have still maintained the improvement. Case 11 was brought on a stretcher as an acute case of katatonia. On admission he could neither walk nor talk, he refused to take his food and was fed nasally for a few days. After the third injection of cardiazol he began to talk and took his food and after the tenth injection he became quite normal and began to walk. He was given a full course of 30 injections—27 or 0.5 gm. and 3 or 1 gm. He improved very much in his mental and physical health and was discharged as fully recovered by the board of visitors. In my opinion this was a great success for cardiazol as the case on admission appeared to be quite hopeless. Of the 15 improved cases 5 have since relapsed after maintaining the improvement for a varying period from 2 to 5 months. The remaining 10 cases have still maintained the improvement and are now working satisfactorily in the hospital. By improvement, I mean those cases who before the treatment were noisy, attitudinistie, negativistie, showing flexibilitas cerea and a few of them were partly living a vegetative existence, improved after cardiazol injections inasmuch as they began to take an interest in their surroundings and in themselves and are now attending the occupational therapy departments in the hospital, to which place they refused to go and work before. Fourteen cases showed no improvement at all in spite of the full course of 20 to 30 injections given to them and they remained stationary. The results of the experiment can be called encouraging and the results in percentages were as follows :—

Full remissions	..	31 per cent
Improved	..	36 " "
Stationary	..	33 " "

All the recovered cases were given four extra injections after recovery as recommended by Dr. Meduna. In all our cases we were able to induce the first fit at an initial dose of 0.5 gm. of cardiazol and in most cases this initial dose failed later and we had to increase the dose in graduations up to 1 gm. One gramme of cardiazol never failed to induce fits in all our patients hence our initial dose for every patient was 0.5 gm. and maximum dose 1 gm.

The diagnostic aid of cardiazol in suspected cases of epilepsy

Dr. Schönmehl (1936) gives an interesting account of cardiazol as an aid to diagnosis in suspected cases of epilepsy and other allied conditions. During his experiments on stuporous conditions in epilepsy he found that fits could be induced in epileptics by very small doses of

cardiazol (0.5 to 3 c.cm.). We also experimented with our epileptic patients with small doses of cardiazol which failed to induce fits in our schizophrenic patients but induced severe fits in epileptic patients. Doses given by us were from 1.5 c.cm. to 3 c.cm. Dr. Meduna states that to produce epileptic fits in a normal healthy individual the dose required would be approximately 10 c.cm. only. In schizophrenic cases we could not induce fits below the minimum dose of 0.5 gm. It therefore proves that the small doses of cardiazol can produce convulsive fits in epileptics only. One of the patients of Dr. Schönmehl had been successful in convincing the authorities when applying for a motor driving licence that he was not a sufferer from epilepsy. He was brought to Dr. Schönmehl who injected a small dose of cardiazol and induced severe fits in him and thus confirmed the diagnosis. We had a patient in the female section who was a suspected case of epilepsy; no medical officer had seen her in a fit because she had occasional fits only during the night and by the time a medical officer was called the patient had recovered from the fit, as she was suffering from a mild type of epilepsy. We therefore decided to use cardiazol in this case and injected 2.5 c.cm. of cardiazol; the patient went into a fit at once. We could not carry out further experiment by cardiazol in this direction as we had no other suspected cases of epilepsy.

Summary

(1) The problem of schizophrenia is very briefly described with its empirical treatment.

(2) Forty-two cases of schizophrenia were treated with cardiazol after the method of Dr. Meduna; the technique fully described.

(3) The results of the experiment were encouraging.

(4) Cardiazol treatment appears to be perfectly safe in selected cases and is well worth a trial in all cases of schizophrenia, and more so in the katatonic and hebephrenic varieties.

(5) It is free from any dangerous complications and does not require such constant medical and nursing attention as in the case of insulin therapy. I would certainly give this treatment preference over insulin therapy.

Acknowledgments.—We are indebted to Messrs. A. G. Knoll for the free supply of cardiazol powder for our experiment.

I should like to acknowledge my appreciation of the valuable help I have received from the medical and nursing staff of the hospital.

I am also indebted to my friend and colleague, Dr. Gyárfas Kalman of Budapest, for the translation of Dr. Meduna's paper.

THE TREATMENT OF ASCARIASIS

By P. A. MAPLESTONE, D.S.O., D.Sc., M.B., B.S., D.T.M.
and

A. K. MUKERJI, M.B. (Cal.)

(From the Helminthological Research Laboratory,
School of Tropical Medicine, Calcutta)

THE comparison of the results of treatment with santonin of Russian and Indian origin, given alone or combined with oil of chenopodium, was reported by Maplestone and Mukerji (1931). It seemed that the combination of the two drugs was slightly better than either alone, so it has been further investigated. In our original work the full dose of santonin given was five grains and of oil of chenopodium fifteen minims. The oil of chenopodium was placed in hard gelatin capsules and the santonin given as a powder, the two drugs being swallowed together with the assistance of a little water, and they were followed in two hours with a dose of magnesium sulphate. This dosage was continued for a time and then it was resolved to reduce the amount of santonin to four grains leaving the amount of oil of chenopodium unchanged. Other series of treatments were successively tried, reducing the santonin first to three grains and then to two grains as the maximum dose, but always given with fifteen minims of oil of chenopodium.

In the table the reduced doses of oil of chenopodium given to children are shown and it should be noted that the dose of santonin was also proportionately reduced from the maximum in each series. For example, seven or eight minims of oil of chenopodium would be accompanied by two and a half grains of santonin when the maximum dose was five grains, but when the maximum dose of santonin was only two grains the amount given with a half dose of oil of chenopodium would be only one grain. The reduction in santonin was, as nearly as possible, kept proportionate to the reduced dose of oil of chenopodium in this way but the minimum amount of santonin given was half a grain in any series.

The figures shown under the maximum dose of five grains of santonin and fifteen minims of oil of chenopodium include those given in the paper quoted above with the addition of a few more treatments. In these early treatments the oil of chenopodium was known to contain at least 60 per cent of ascaridole, and after its standardization, which occurred about the time our series with four grains of santonin as a maximum was commenced, all the oil used has been of *British Pharmacopœia* standard.

Wilson, I. G. H. (1936). *A Study of Hypoglycæmic Shock Treatment in Schizophrenia*. His Majesty's Stationery Office, London.

The table needs little comment as the results are fairly evident. The main point that emerges is that the reduction in the amount of santonin appears to have little effect on the result of treatment when it is combined with oil of chenopodium, but the reduction in the amount of oil of chenopodium has this effect and is indicated in all the series by the reduced cure rate in children compared with adults. When only the full doses of both drugs are considered it will be seen that the cure rate in 33 out-patients who had two grains of santonin is 81.8 per cent whereas all the other full doses of santonin combined with fifteen minims of oil of chenopodium give a cure rate of at least 94 per cent and the mean cure rate for all full dose treatments is 91.9 per cent. Statistically the low cure rate of 81.8 per cent with two grains of santonin in the 33 out-patients is not found to be 'significant' compared with the higher rates obtained with other doses. When the reduced doses of oil of chenopodium are considered it is found that the low cure rate from the 9-8 minim group onwards is definitely 'significant' but that the rate of 83.3 per cent in the 12-10 minim group is not 'significantly' lower than for the 15 minim group, but this does not invalidate the general conclusion that the fall in cure rate varies directly with the reduction in the dose of oil of chenopodium.

In a vertical column at the end of the table the cure rate for the various groups of cases classified according to the full dose of santonin is shown and it will be seen that the variation is very slight and quite irregular thus further confirming the contention that the dose of oil of chenopodium has a much greater bearing on the cure rate than that of santonin, when the two drugs are given together.

In the case of most drugs the therapeutic effect varies directly with the size of the dose and the size (or weight) of the patient so that corresponding effects are obtained in adults and children by reducing the dose proportionately on this basis. This principle does not appear to operate in the case of oil of chenopodium, but it is really the worms living free in the intestines and not the patient that are being treated. The worms are just as large in children as they are in adults so this may partly explain the comparative inefficiency of small doses of oil of chenopodium in children. It cannot be the full explanation, however, because the smaller volume of the child's intestine should give a concentration of the drug in a reduced dose approximately equal to that given by a full dose in the intestine of an adult. Another explanation of this discrepancy, that we offered in our former paper, is that the majority of intestinal helminths more readily infect young animals than adults, and from this it may be deduced that the power of these worms of maintaining themselves is greater in the more susceptible child than it is in the more resistant adult,

A CLINICAL INVESTIGATION ON THE VALUE OF PROSEPTASINE AS A PROPHYLACTIC IN PUERPERAL INFECTION

By S. N. HAYES, F.R.C.S., F.C.O.G.

LIEUTENANT-COLONEL, I.M.S.

Medical Superintendent, Lady Willingdon Hospital
and

ABDUS SAMI, M.S. (Punjab), M.B., B.S.
Lady Willingdon Hospital, Lahore

THE last three years have seen spectacular changes in, and a revival of, the chemotherapeutic treatment of streptococcal infections.

Domagk in 1935 showed that a red dye, the hydrochloride of 4'sulphamido-2:diamino-azo-benzol, when administered orally prevented death in mice that had been inoculated intraperitoneally with hæmolytic streptococci. This dye was marketed under the name of Prontosil and was immediately used and reported on by Colebrook and his co-workers (1936) in the treatment of streptococcal infections of labour and the puerperium.

Colebrook (1937) indicates the probability that the simpler derivatives (now classed as sulphanilamides) would prove to be the active principle of the azo dyes. He also expressed the hope that the sulphanilamides would exert a prophylactic effect on hæmolytic streptococci and has shown experimentally that para-amino-benzene sulphonamide confers considerable bactericidal power upon human blood when added to it *in vitro*, and that in order to protect animals it was necessary for an effective dose of the drug to have been given within a few hours (not more than six) before the animals were infected.

The carefully-recorded cases and conclusions of Colebrook and his co-workers indicate that the diazo compounds act at their optimum efficiency if administered before tissue invasion has occurred. Our own clinical experience coincides with these conclusions. Where tissue invasion has occurred we are not, as yet, impressed with the results obtained by treatment with the diazo compounds.

Hospital midwifery practice in India is peculiar in that it deals with a large number of potentially or frankly infected cases. Most of the emergency cases admitted to hospital have received attention from trained or untrained *dais*, varying from a few vaginal examinations to manipulative interference resulting in a patient almost completely moribund. In our

hence they are not so easily dislodged from the former as they are from the latter by the same treatment.

own clinic during 1937 no less than 479 out of 663 were classed as emergency. The morbidity for the years prior to 1935 varied from 22 per cent to 25 per cent and this includes only those cases in which the infection was of genital origin.

Although a curative drug is of undoubted value, we consider that under existing conditions a prophylactic one is of even greater value, and that, if a drug when administered prophylactically causes a marked reduction in the morbidity rate, it is worthy of consideration and careful investigation. We have during 1937 administered proseptasine prophylactically to all emergency cases admitted to hospital. For this purpose Messrs. May and Baker kindly supplied us with adequate supplies of the drug.
